THE

CYCLOPÆDIA

OF

PRACTICAL MEDICINE.

EMETICS. (Φάρμακα ἐμετικά, *emetica*; from ἐμέω, *vomo*.) Emetics may be defined—substances which cause the ejection of the contents of the stomach by the mouth, independently of the stimulus of quantity, or of the influence of any nauseous taste or flavour. When these substances, with a few exceptions, are taken into the stomach in certain quantities, they do not immediately operate, but produce an uneasy sensation attended with nausea, which increases, and terminates in vomiting. Even before vomiting commences, the influence of the emetic substance is not confined to the stomach. As soon as the nausea is felt, the countenance becomes pale; and the pulse, diminished in strength and frequency, is quick and irregular. There is occasionally great anxiety, listlessness, and depression of spirits, with a tendency to fainting: at length sweat breaks forth, and just before vomiting commences, a peculiar sensation is experienced at the clavicles. After the vomiting has begun, the face flushes, the pulse is quickened, and it remains so betwixt each effort of vomiting, which occurs several times in succession, at short intervals, before it ceases. The nausea now subsides, either at once or by degrees, leaving a transitory feeling of depression, which makes the patient indifferent to every thing around him.

When emetic substances, with the few exceptions to which we have already alluded, are received into the stomach, they do not operate by any local stimulating influence on the coats of that organ; the time which elapses after they are swallowed sets aside such an opinion; and there exist other sufficient reasons for affirming that they are absorbed and carried into the circulation before vomiting is induced. When a solution of tartar emetic is injected into the jugular vein, it produces vomiting

sooner than if it had been swallowed; and an experiment of M. Majendie has demonstrated that vomiting produced by an emetic substance may be stopped by pressure made upon the medulla oblongata. Now the inference that may be drawn from this fact is, that the action of emetics is not owing to any local stimulus on the nerves of the stomach, but to the action of the emetic substance, after being absorbed into the circulation, as a direct stimulus to the origin of the nerves, whereby contractions of the stomach, and the actions of the other muscles concerned in the act of vomiting, are induced. These nerves comprehend a branch of the eighth pair, the intercostal, and the phrenic nerves.

It may be inquired—what is the nature of the irritation which excites vomiting? Does it depend on the physical character of the particles of the substance employed? or is it the result of some chemical or electro-chemical change? These are queries which cannot be satisfactorily answered: all that can be said is, that there is, probably, something connected with the substances which cause vomiting, which has the power of irritating a particular set of nerves only: for, were this not the case, why should tartar emetic, when injected into the jugular veins, excite vomiting?

Vomiting may be produced by a variety of causes, either connected directly with the stomach itself, or indirectly, by sympathy with it through the medium of the nervous system.

1. Vomiting may be directly induced by food undergoing changes inconsistent with healthy digestion; by mechanical irritants lodging in the stomach; by tumours pressing on the pylorus; by inverted actions of the intestinal canal, forcing the contents of the duodenum, particularly the bile discharged into it from the biliary duct, into the stomach; by chemical acids and other poisons, or emetic

substances taken into it; by any the mildest substances, when inflammation of its coats, or ulceration, augments its nervous irritability.

2. Vomiting may be indirectly induced by strangulations of the intestinal canal; by the irritation arising from biliary or renal calculi impacted in the excretory ducts of the liver or of the kidneys; by titillation of the fauces; by inflammation of certain portions of the contents of the cranium, for example, of the arachnoid membrane covering the base of the brain; by repelled cutaneous eruptions; by emetic substances injected into the veins; by sailing, swinging, riding in a carriage, and other movements of the body; by pregnancy; by the influence of certain odours; and by mental impressions. Whichever of these causes produces vomiting, a specific action of the stomach, and the consent of certain muscles of the thorax and the abdomen are, in every instance, necessary to produce the effect; thence the question, in what manner is vomiting effected? In replying to this query, let us first inquire what opinions have been advanced regarding it by others.

M. Chirac* first suggested the opinion that the stomach is passive during vomiting, which he contends is effected solely by the action of the diaphragm and the abdominal muscles; an opinion afterwards adopted by Duverney, Bayle, and John Hunter. M. Litre denied the influence of the abdominal muscles, and maintained that the diaphragm is the chief agent in producing vomiting. Lieutaud and Haller supported the idea that the stomach is the real agent; the former founding his opinion on having observed, in a patient who could not be made to vomit by the most powerful emetics, that the stomach was greatly distended and insensible. Sir Charles Bell† appears to hold nearly similar opinions to those of Lieutaud upon this subject. "That vomiting," says he, "may be produced by the inverted motion of the stomach and diaphragm alone, is apparent from experiments upon living animals, where the abdominal muscles are laid open, and from cases in which the stomach has rested in the thorax, and yet been excited to active vomiting." He also states that the walls of a stomach in his possession "had become so thick that they could no longer suffer contraction by the muscular fibres; the consequence of which was, that although the inner coat of the stomach was in a raw and ulcerated state, there was no vomiting." Sir Charles, however, modifies this opinion by remarking, "that when the stomach is excited to vomiting, there is consent of the abdominal muscles, by which they are brought into violent spasmodic action; not alternating in their action, as in the motion of respiration, but acting synchronously, so as greatly to assist in compressing the stomach; but," he adds, "at the same time, the action of these muscles, however forcible their contraction, cannot alone cause vomiting; nor has this action any tendency to produce such an

effect on other occasions, in which the utmost contraction of the diaphragm and abdominal muscles is required to the compression of the viscera."

M. Majendie, in an able memoir published in 1813, supports the opinion of Chirac.* In one of his experiments, he drew the stomach through an opening of the abdomen, thus freeing it from the influence of the diaphragm and abdominal muscles, and he found that vomiting could not be excited. He also ascertained that, if all the abdominal muscles be removed, leaving only the linea alba, vomiting still occurs from the stomach being pressed, as he supposes, between that part and the diaphragm. In another experiment he states that he substituted a pig's bladder for the stomach, and, nevertheless, vomiting took place! He found that the division of the phrenic nerve weakens the action of vomiting, but does not altogether prevent it.

These experiments prove—1. that the influence of the nervous system is essential to the production of vomiting; 2. that the abdominal muscles greatly influence the ejection of the contents of the stomach. But they do not satisfactorily explain the action of the diaphragm, nor the part which the œsophagus bears in the operation of vomiting. Dr. Richard Harrison, in his Gultonian Lecture, adopts the opinions of Chirac and Majendie, as far as regards the action of the diaphragm and the abdominal muscles; but he adds to this call upon the expiratory muscles through the agency of the brain, and their consequent action, the contraction of the stomach itself. There can be no doubt of the agency of the nervous system in this operation; the only question is, whether the excitement be first exerted on the extremities of the nerves of the stomach itself, from which the impression is communicated to the brain by sympathy, and the auxiliary muscles be thus called into action: or whether, as the writer of this article imagines to be the case, the impression is made upon the spinal marrow from the absorption of the emetic substances, and through the influence of the motor nerves to the respiratory muscles, so that all the machinery concerned in the operation is excited into simultaneous action.

Dr. Marshall Hall has endeavoured to prove that Majendie's assertions respecting the influence of the diaphragm are incorrect, and that the act of vomiting is in fact a forcible expiratory effort. He contends that, if the diaphragm contracted, as Majendie affirms, the act of vomiting would be attended by inspiration; that the glottis, in such a case, would necessarily be open, and that the fluids ejected from the stomach would be drawn into the larynx, and induce great irritation there; an event which does not occur in vomiting. On the contrary, as M. Majendie admits, although he contends for the agency of the diaphragm, the larynx is accurately closed at the instant that the vomited matter is passing through the pharynx. Dr. Hall's explanation of the mechanism

* Histoire de l'Académie des Sciences, 1686.

† Anatomy of the Human Body, vol. iv. p. 54.

* See also Précis Élémentaire de Physiologie vol. ii. p. 140.

of vomiting is this: "the contents of the thorax and abdomen are subjected to sudden and almost spasmodic contraction of all the muscles of expiration, the larynx being closed so that no air can escape from the chest, and the two cavities being made one by the floating or inert condition of the diaphragm." The mere mechanism of vomiting, therefore, according to Dr. Hall, "differs little from that of coughing, by which indeed the contents of the stomach are frequently expelled: the larynx in the former is, however, permanently, in the latter, only momentarily closed; and there is doubtless a different condition of the cardiac orifice and of the œsophagus." In order to confirm his opinion, Dr. Hall made an opening into the trachea of a dog, which was excited to vomit by subsulphate of mercury; during the act of vomiting, the air from the lungs was forcibly driven through the artificial opening. Dr. Hall, in his explanation, admits the influence of the œsophagus, and adds, "it is plain that the cardiac orifice must be freely opened; for mere pressure upon the viscera of the abdomen will not, in ordinary circumstances, evacuate the contents of the stomach. To effect this open state of the cardiac orifice, it is probably necessary that the diaphragm should, indeed, be in a relaxed rather than in a contracted state." There is much ingenuity and considerable truth in this theory; but it does not wholly explain the operation of vomiting. The following opinion of the author of this article may be regarded as a modification of that of Dr. Hall.

He admits that it is true the glottis is closed, and that a powerful effort is made as if of expiration; but this effort is not altogether that of expiration; for, whilst there is a powerful and sudden contraction of the abdominal muscles, forcing up the whole contents of the abdomen towards the thorax, the diaphragm is fixed, owing to the closing of the larynx, and the retention of the quantity of air which the lungs contained at the commencement of the effort. The diaphragm is thus prevented from ascending into the chest; and the pharynx being drawn up as in the act of deglutition, opens the cardiac orifice of the stomach, and forms with this viscus one continuous cavity. This open state of the cardiac orifice of the stomach, forming one continuous cavity of the stomach and pharynx, explains an observation of M. Majendie, that "during the state of nausea which preceded vomiting, in some of his experiments, air was drawn into the stomach." Now, if it be true that the cardiac orifice of the stomach is open, and the mouth, the œsophagus, and the stomach be one continuous cavity, it is evident that the external air, which is heavier than the air and vapour contained in the stomach, will necessarily be forced into this organ by its mere gravity, as it would be into an ordinary receiver containing vapour and little or no air. In this state, by the sudden compression of the stomach by the abdominal muscles drawn forcibly and suddenly inwards, the diaphragm being fixed, the contents of the stomach must be directed up-

wards, with a degree of force commensurate to the suddenness of the pressure upon its walls; and consequently they are thus ejected by the mouth. If this description be correct, it is evident that the act of vomiting is the result of the simultaneous action of all the muscles of respiration, at a moment when the glottis is shut, and offers resistance to the ascent of the diaphragm. Dr. M. Hall is correct in describing it as an expiratory effort; but this effort alone would not effect vomiting, were there not the resistance which has been described opposed to it. The stomach, therefore, is in every respect passive; and it is not obvious that contraction of that organ forms any part of the process of vomiting; it is rather in a state of relaxation than of contraction. Thus, if a bag half filled with fluid, with an open tube rising from it, were suddenly struck or compressed, the fluid would be ejected through the tube; but, if at the same time, the bag was also contracting its general capacity, the impulse of the compressing force would be necessarily diminished, and the impetus of the ejection of the fluid considerably weakened.

Such is the view of this operation taken by the writer of this article; but in whatever manner it is accomplished, there can be only one opinion respecting the share which the nervous system has in the operation. "This act, (vomiting,) will not take place," justly remarks Dr. Paris, "however forcibly the stomach may be goaded by emetics, where the energy of the nervous system is suspended, as in cases of profound intoxication, or in violent wounds and contusions of the head; while, if the brain be only partially influenced, as by incipient intoxication, or by a less violent blow upon the head, its irritability is increased instead of being paralysed, and vomiting under such circumstances is excited by the slightest causes."*

The first effect of the influence of an emetic on the system is the production of nausea, and a consequent diminution of general excitement: this is followed by the ejection of the contents of the stomach, and an alteration in the condition of its secreted fluids: thus, for example, in dyspepsia not only do emetics eject any superabundant acid contained in the stomach; but they also so influence the functions of the secreting follicles, that for some time all acid totally disappears. Along with the contents of the stomach, bile is also generally ejected, owing to the compression of the liver and the gall-bladder forcing a large quantity of this secreted fluid into the duodenum and the stomach. In the act of vomiting, also, all the abdominal viscera being compressed, the blood is propelled more forcibly through their vessels; thence a change is effected on the intestinal secretions, and on those of the pancreas and the spleen: even the kidneys are affected, and the quantity of urine is considerably increased. The pulmonary system is also influenced, a freer circulation of the blood through the lungs is promoted, and the action of the secreting and exhalant vessels is augmented. But, besides these effects of

* Pharmacologia.

emetics on the particular organs, the result of their influence on the general system is the equable distribution of the blood to every part of the body; and the consequent removal of local determinations and congestions. How far these effects depend in part upon the absorption of the emetic substance is yet to be ascertained.

Emetics operate as evacuates in other respects than by emptying the stomach; they induce diaphoresis, and by stimulating the capillary system, and thereby checking the effusion of serous fluids into the cavities of the body, enable the absorbents to carry off any fluid already accumulated there: thence their utility in dropsical affections. By the nausea, also, which attends their operation, abating the force of the circulation, they have sometimes proved useful in active hemorrhages.

Although all the substances classed as emetics accord in producing more or less nausea and vomiting, yet they differ in some circumstances.

1. *Emetics differ in the time required for producing their effects.*—The sulphates of zinc and of copper operate the quickest of all the emetic substances in common use, exciting vomiting almost as soon as they are swallowed. Tartar emetic, and the other active antimonial preparations, and subsulphate of mercury, operate quickly also, but less so than the salts of zinc and of copper; whilst all the vegetable emetics are still more tardy in producing vomiting. This diversity in point of time has not been satisfactorily explained: it has been supposed to depend on the solubility of the emetic substance in the gastric juice, and its consequent application to the extremities of the nerves of the stomach being thus more or less facilitated. But, independently of the fact that all emetics, with the exception of the few which operate by their direct influence on the nerves of the stomach, are absorbed before they produce their effects, there is no evidence of this action of the gastric juice; and substances already in a state of solution are influenced by the circumstances, whatever these may be, which produce this diversity. Two substances held in solution in the same solvent, and conveyed into the stomach under the same circumstances, differ considerably in the time which elapses before they operate. Thus a solution of tartar-emetic in wine operates sooner than a vinous solution of ipecacuanha; although, were both these substances in the solid state, and were the action of the gastric juice on them requisite for their operation, it is probable that the vegetable substance would be the most readily dissolved, and consequently operate most quickly; but the reverse is the case. It is probable that the diversity depends on the more rapid absorption of the antimonial salt than that of the emetina, the active principle of the ipecacuanha, after both have passed the pylorus. The time required for the operation of different emetics should be familiar to the physician, as much of the benefit to be expected from this order of remedies sometimes depends upon this circumstance.

2. *Emetics differ in the degree and the severity of their effects.*—The saline emetics in general operate more violently than the vegetable emetics; but the latter cause a more severe and longer continued nausea. It is not easy to account for these effects, unless we admit that, although the first impression of the saline emetic on the nervous system be the most energetic, yet, that the saline substance is more readily decomposed, or thrown out of the system, than the vegetable.

It is of much importance, in a practical point of view, to attend to the degree of energy of operation of different emetics, and to avoid any risk connected with their violent action. Emetics do not operate with much energy on persons of torpid habits; larger doses are required than in ordinary cases; and, not unfrequently, vomiting cannot be excited by any dose. When this is the case, emetics cause great anxiety and uneasiness. Persons of a sanguine habit are more easily affected by emetics than those of a melancholic; women than men; children than adults: thence experience has informed us that, in febrile affections, vomiting is a common symptom in such persons. It is of some importance to know how to anticipate the degree of difficulty or facility with which different persons can be excited to vomit, seeing that not only those who are not easily excited suffer from pain and anxiety, but those who are very easily affected are apt to be injured by even the ordinary dose of an emetic.

Emetics are contra-indicated in some conditions of the system. In all cases in which the phlogistic diathesis prevails, they ought not to be administered until after bloodletting and purging have been employed. They have, nevertheless, been found very beneficial in some inflammatory affections. In croup they are supposed to be specially indicated: Dr. Crawford, and many subsequent writers on that disease, recommend them to be administered in the earliest stage of it; others, however, urge the propriety of waiting until the inflammatory action be at least mitigated by the use of the lancet, calomel, and purgatives. In those cases in which we have seen them employed in the commencement of the disease, much less assistance has been required from bloodletting than when they have not been given. We must admit, however, that when the inflammatory symptoms run high, they are at least of doubtful efficacy. In pneumonic affections, also, if the state of the bronchial cavities require the influence of an emetic to aid expectoration, they ought not to be employed until after the excitement has been reduced by the proper use of the lancet. As pressure is necessarily applied to the descending aorta during the action of vomiting, there is a temporary interruption to the pulmonary circulation, and the blood is returned with difficulty from the head; consequently vomiting should not be excited in states of the habit predisposing to apoplexy. From the compression, also, of the abdominal viscera, the administration of emetics requires caution in those afflicted with hernia and prolapsus of the anus or of the uterus; nor are they always ad-

missible in the advanced stage of pregnancy. The spontaneous vomitings which attend the early stage of pregnancy are sufficient guarantees of their safety at that period. In diseases of debility, and in weak and delicate subjects, emetics, especially those which nauseate, should be carefully avoided. Experience has also proved that the frequent employment of emetics is injurious, producing general debility, and such an irritable state of stomach that it is excited to vomiting by the most trifling causes, even by changes in the nature of the food; indeed no means are so likely to induce dyspepsia as the custom of taking frequent emetics.*

With respect to the period of the administering emetics, much must depend on the circumstances of the case which demand their employment.† If there be no immediate urgency, the evening is the best time; for as the body is always more or less exhausted by the operation of an emetic, the tendency to sleep which supervenes can then be readily indulged. Attention to the period for administering emetics is particularly requisite in febrile affections. Thus when they are necessary in continued fever, the time of day for administering them with most advantage must not be overlooked. In almost every continued fever there is a mid-day and an evening exacerbation. These are not always very obvious; the evening one, however, is the most so; and its approach is marked by increase of pulse, thirst, headach and dry hot skin. It is immediately prior to this accession that emetics will be found most useful, sometimes checking it altogether, at other times at least diminishing its violence.

In reference to the operation of emetics, we may remark that the dose of the emetic substance should be sufficient to produce full vomiting, otherwise nausea and restlessness, instead of vomiting, will follow the administration of the medicine. It is the custom to order warm water to be freely drunk during the operation of an emetic. This certainly promotes its action if the fluid be taken after each time of vomiting; but it is requisite to be cautious that too much is not taken at once. The stomach, when oppressed with water, does not yield to the action of the muscles which are excited to produce vomiting, thence it is in danger

of laceration. There are several instances on record of this having occurred; but it may be questioned whether rupture ever happened, unless the organ was previously diseased? The quantity of fluid for an adult should not exceed two thirds of a pint at a draught; it should be tepid, and, if the stomach be weak, some bitter infusion, as, for instance, that of camomile flowers, or a few drops of liquor ammonia in the water, should be employed to aid the action of the emetic. If the vomiting be severe and long-continued, it may be checked by solutions of neutral salts; sulphate of magnesia for example, or citrate of potassa, formed with the carbonate of potassa and *fresh* lemon-juice, given in a state of effervescence; or a teaspoonful of magnesia may be given in a glass of sherry; or solid opium or hydrocyanic acid may be administered in small doses.*

All substances employed to excite vomiting may be arranged in two classes—*direct* and *indirect* emetics.

I. *Direct emetics* are substances which cause vomiting by an immediate impression on the nerves of the stomach. It may be asked how can this take place, if the stomach be a passive agent in the act of vomiting? We reply, that by the term passive agent we do not mean to assert that the stomach is insensible to the stimulus of all emetic substances; on the contrary all irritants, whether chemical or mechanical, are capable of stimulating the stomach to vomiting; but, nevertheless, in this operation, the stomach is not the active agent. This seeming inconsistency may be thus explained. When the stomach is in the performance of its natural function, the digested food is pushed forward to the pyloric orifice; but if the chymification be not complete, it is again thrown back into the fundus, and occasionally into the pharynx, producing eructation; a circumstance, however, which occurs only when the secreted juices of the stomach are in a morbid state; and, under this condition, the ejection resembles in every thing but degree that produced by emetics. In a similar manner, when a large dose of sulphate of zinc, for instance, is swallowed, its immediate application to the nerves of the fundus of the stomach, produces a spasmodic contraction there, which throws the whole contents of the viscus mixed with the sulphate upon the pylorus; but these are as rapidly returned, even before the relaxation which must follow the spasmodic contraction have taken place; and by this means, the emetic substance being applied to the nerves of the cardiac portion of the stomach, the muscles and every other part necessary for effecting vomiting are simultaneously called into operation, and vomiting takes place. This is the opinion of the writer of this article, and he conceives that it is the only theory capable of explaining the imme-

* This remark is, apparently, at variance with the custom of the Romans. Emetics were daily taken to enable them to relish the enjoyments of the table; and so far did the Romans carry this custom that they sometimes excited vomiting to eject from the stomach what they had eaten in one course, that they might be the more capable of enjoying what was to follow. According to Seneca, "they vomited that they might eat, and ate that they might vomit." They employed emetics before meals that they might be able to eat more plentifully; and they often concluded a feast with an emetic to prevent the consequences of gluttony. In one of Cicero's epistles to Atticus, he describes a visit which he made to Cæsar, at his villa near Rome; and states that his dignified host paid him the compliment of taking an emetic before dinner when he understood that Cicero intended to spend the day with him.

† Some of the old writers, Stoll in particular, regard the period of the day as a matter of indifference. Rat. Med. 11.

* Many other means may be employed to check vomiting; as, for instance, the administration of subnitrate of bismuth, infusion of calumba, strong coffee, tincture of capsicum diluted with water, in that induced by pregnancy and sailing;—a large dose of calomel, and dry cupping on the epigastrium.

diate emetic influence of sulphate of zinc, sulphate or acetate of copper, and carbonate of ammonia. These substances, when taken into the stomach, first hasten, in a spasmodic degree, that action of the organ which carries the food forward to the pylorus; and there acting *contra naturam*, instead of opening the pyloric orifice, they are thrown back upon the cardiac portion of the stomach, the nerves of which being suddenly impressed, call into play all those sympathies which operate to produce the action of vomiting. If this theory be admitted, it may be applied to explain not only the vomiting caused by powerful irritants when swallowed, but those also which occur in cancerous affections of the pylorus, and in the early stages of pregnancy. Thus, in cancer of the pylorus, when food is taken into the stomach, no vomiting occurs until it is pushed forward to the pylorus, which, being morbidly excitable, throws back the food mixed with acrid matters the result of the disease, and these acting on the sentient extremities of the eighth pair of nerves spread on the cardiac portion of the stomach, the muscles of the abdomen and those of respiration are instantly called into action to relieve the stomach of the offending matter. In pregnancy, again, the sympathy between the stomach and uterus is such, that the disturbance of the former is in the direct ratio of the energy of the latter; digestion, therefore, becomes depraved, the chyme is imperfectly formed, and, mixed with the acrid secretion, is thrown back from the pylorus, and applied to the cardiac nerves, and vomiting is necessarily excited.

Substances which act in the manner just described are those which constitute *direct emetics*. Their operation is preceded by no nausea, neither is any left behind after it is completed. Emetics of this division, therefore, are adapted for producing full and immediate vomiting, in those conditions of the habit in which the exhaustion caused by nausea would be injurious, but in which it is nevertheless necessary to unload the stomach. They are also the most useful in cases of poisoning, not only on account of the rapidity of their operation, but from their action not being followed by absorption, which, in such instances, would prove highly prejudicial. Direct emetics are few in number, and are all inorganic substances.

1. *Ammonia*. If the official solution of ammonia, to the extent of half a fluid drachm, be swallowed in a cupful of cold water, and the same quantity of tepid water be taken immediately afterwards, it excites instant vomiting. But as untoward circumstances have occasionally followed the administration of the solution of pure ammonia, it is rarely employed as an emetic; the carbonate, in doses of from 3℥ to 3i being given in its stead. It has been found serviceable in those cases of chronic catarrh, in greatly debilitated habits, in which expectorants cannot with propriety be administered. In such a state of the system, the act of vomiting, induced by the ammonia, aids in unloading the bronchial tubes, whilst, at the same time, a salutary stimulus is given to the nervous system; and the expectoration, which in

general is suspended in such cases, is again brought on. When administered in larger doses, ammonia operates as an irritant poison, and requires the immediate administration of vinegar to neutralize and obtund its acrimony. (See TOXICOLOGY.)

2. *Sulphate of zinc*. This is a more safe direct emetic than ammonia, and equally powerful in its effects. It excites no nausea, and operates as soon as it enters the stomach, producing a single but copious ejection: it is, therefore, well adapted for cases of poisoning, and to excite vomiting in the commencement of the paroxysm of ague, when we are desirous of breaking the morbid association which keeps up the disease, by giving such an impulse to the system as will propel the blood to the surface, and equalize the circulation. In cynanche tonsillaris, when abscess forms in a situation which cannot be readily reached by the knife, and yet does not seem disposed to break, as the object of prescribing an emetic is merely to burst the abscess, the sulphate of zinc is to be preferred to any other substance. The dose of the sulphate to produce full vomiting is from ʒi to 3℥. If an overdose have been taken, the best antidotes are cretaceous mixtures, milk, and albumen, after the use of the stomach pump.

3. *Salts of copper*. Both sulphate and acetate of copper operate as powerful direct emetics. They have been employed in the incipient stage of phthisis; and it is a curious fact that in this disease the sulphate will sometimes lie in the stomach for upwards of half an hour without producing vomiting, and then operate at once, and as forcibly as when it acts in the usual manner. We may be here permitted to remark that emetics have been regarded as specifics, and have been prescribed in every stage of this disease. "It is remarkable," says Dr. Young, "that a very great majority of the cures of consumption, which are related by different authors, have either been performed by emetics or by decidedly nauseating remedies."* They were employed in this disease by Hippocrates, whose emetic was a compound of honey, vinegar, and water;† and by Galen, who followed the example set by the father of physic. Bennett, Morton, Etmuller, Wainwright, Russell, Bryan Robinson, Marryat, Donald Monro, Macbride, and many other equally distinguished physicians speak also favourably of their effects. The confidence of Dr. Reid and Dr. Simmons in the use of emetics in phthisis was unbounded. Dr. Mackittrick Adair held almost as sanguine an opinion of their beneficial influence as Dr. Reid: he gave first a pint of warm water, then a grain of sulphate of copper with a drop of dilute sulphuric acid in half an ounce of water every other evening for three days; then every morning.‡ Notwithstanding these strong testimonies, truth obliges us to state that the method of treating phthisis with emetics has not suc-

ceeded in our hands, nor in those of many of the most distinguished men who, at different periods, have adorned the profession. If emetics, however, be employed, those which operate directly, the sulphates of zinc and of copper, should be preferred. The dose of the sulphate of copper is from ten to fifteen grains dissolved in three ounces of water. In cases where it has been overdosed, the best antidotes, after the use of the stomach-pump, are ferrocyanate of potassa, milk and albumen.

II. *Indirect emetics* are obtained both from the organic and inorganic kingdoms of nature. Indeed, whatever disturbs the energy of the brain to a degree sufficient to affect the stomach by nervous sympathy, and to call into action the muscles necessary to establish the act of vomiting, may be regarded as an indirect emetic. Thus the mechanical irritation of the uvula and velum of the palate with a feather or with the finger; the motion of a carriage, swinging, whirling, sailing, and many narcotics, produce nausea and vomiting; and the same effects result from inhaling some gases.

Among the organic substances which operate as indirect emetics are some varieties of acrid oil, in combination with resin and other principles, as found in the cotyledons of *sinapis nigra*, the flowers of *anthemis nobilis*, and the leaves of *asarum Europæum*.

1. *Mustard*. A table-spoonful of flour of mustard mixed in water forms a ready and useful emetic, in cases which admit of stimulants: it operates quickly, and with less nausea than the direct emetics. This dose is rather large if the flour of mustard be genuine; but that usually sold in the shops contains, according to Dr. Paris, one sixth part only of genuine mustard. Emetics of flour of mustard are useful in cases of intoxication threatening apoplexy, as the stimulant property of the mustard proves beneficial after its emetic operation is over. In the atonic form of gout, also, in which no irritation is more hurtful than that arising from crude undigested matters in the stomach, a mustard emetic may prove highly beneficial, or at least the substance employed to excite vomiting, in such a case, should be of a warm stimulant kind, the operation of which is not followed by debility. For the same reason, no emetic is so well suited for cases of malignant cholera as mustard.

2. *Camomile flowers*. A strong tepid infusion of these flowers is powerfully emetic, when administered in doses of from $f\text{ʒ}iii$ to $f\text{ʒ}iv$; and a weaker infusion is well adapted for promoting the action of other emetics, when the stomach is weak and likely to be oppressed by the use of tepid water.

3. *Asarabaca*. This plant owes its emetic property to a combination of acrid oil and cytissina.*

* This peculiar principle received its name from having been first obtained from the seeds of the cytissus *laburnum* by MM. Chevallier and Lasaigne. In a separate state it is of a yellow colour, has a nauseous bitter taste, attracts moisture from the air, dissolves readily in water, less so in alcohol, and is totally insoluble in ether. It is better known from its negative than its positive qualities, as none

It is very seldom employed, as it loses much of its emetic power by drying and keeping.

4. *Emetina*. A more common indirect emetic than either of the three substances already mentioned is *emetina*, as contained in the roots of *ipecacuanha*, (*cephaelis ipecacuanha*.*) This principle operates more quickly as an emetic than the root which yields it, and its action is followed by sweating and a tendency to sleep. It has not been much employed in this country, but the French physicians prefer it to *ipecacuanha*. It is ordered in a solution of four or five grains in six fluid ounces of water, of which two fluid ounces are ordered to be taken every half hour until full vomiting is procured. That it operates on the nerves through the medium of absorption has been demonstrated by injecting a minute portion of it into the jugular veins, the cavity of the pleura, the tissue of the muscles, and the anus of a dog; in all of which modes of applying it, vomiting is produced. If it be overdosed, dangerous, sometimes fatal effects ensue: when the latter occur, it excites inflammation of the mucous membrane of the alimentary canal, and the lungs are found gorged with blood, and approaching to hepatization. The best antidote is infusion of galls, which, by forming an insoluble precipitate with the *emetina*, neutralizes and renders it inert.

5. *Ipecacuanha root*, *radix cephaelis ipecacuanha*, which owes its emetic properties to the principle just described, has been known in Europe as an emetic since the middle of the seventeenth century.† It is administered in the form of powder, infusion in water, and solution in wine. The powder is the cortical part of the root, the central or ligneous part being inert: it should be of a bright grey colour, have a nauseating disagreeable odour, and a bitter acrid taste which remains in the throat.‡

of the re-agents which usually precipitate bitter vegetable infusions make the least change in it; nor does it display either acid or alkaline properties.

* *Emetina* is procured from *ipecacuanha* by treating the powdered root with cold distilled water until it ceases to take up any more soluble matter. This watery infusion is then to be concentrated by evaporation in a water-bath; subcarbonate of magnesia added to it in excess, and the evaporation continued to dryness; after which it is to be treated with strong alcohol, and the extract thus procured again treated with water, and evaporated to dryness. In its pure state *emetina* is white, pulverulent, unalterable in the air, scarcely soluble in cold water, soluble in hot water and in alcohol, but not in ether. Its taste is slightly bitter, and it displays alkaline properties. It is usually, however, procured in the form of brown scales, semitransparent, with an odour resembling caromel, and a bitter slightly acrid taste. It is a compound of carbon, hydrogen, oxygen, and nitrogen. Gallic acid, and infusion or tincture of galls precipitate from its solutions in an insoluble form; and it is also thrown down by tincture of iodine, subacetate of lead, bichloride of mercury, and muriate of tin. When it is separated from the *ipecacuanha*, what remains is inert. It was discovered by M. Pelletier in 1817.

† The name of the root is a compound of two Peruvian words, *ipe* signifying root, and *Cuanha* the name of the place where it was first found.

‡ Owing to a peculiar idiosyncrasy, some persons are affected with severe dyspnoea by the odour of *ipecacuanha*. (See ASTHMA.)

In doses of from \mathfrak{z} i to $3\mathfrak{z}$ it produces full vomiting. If $3\mathfrak{z}$ of the powder be triturated with \mathfrak{f} vi of water, and \mathfrak{f} ziii of the solution administered at the distance of half an hour, full vomiting generally follows the second dose. The vinous infusion is chiefly ordered for children in doses of \mathfrak{f} ziii, repeated every fifteen minutes until vomiting be produced.

When ipecacuanha in any form is taken into the stomach, its first effect is on the mucous membrane as a local irritant: it is, however, partially digested in the stomach, and the emetina thus separated is absorbed and produces that simultaneous action of the muscles of the abdomen, the thorax, and the diaphragm, which constitutes vomiting. But, sometimes, in the largest doses, it fails to produce this effect; a circumstance which, if the drug be genuine, can only be attributed to idiosyncrasy. In administering ipecacuanha, or its active principle, as an emetic, it may be given with the intention of either simply unloading the stomach, or of acting sympathetically on more distant organs after it has performed its emetic effect. When prescribed with the first intention, it frequently operates also on the bowels, owing to some of it being forced beyond the pylorus in the first effort of vomiting; and on this account, when added to jalap, the purgative properties of this drug are much augmented. When it is desirable to extend its action after vomiting, this part of its operation should be less aided with tepid water than when vomiting only is required; the result is a powerful determination to the surface and copious perspiration, from the continuation of nausea after its emetic effect has ceased. The question has frequently been discussed, whether ipecacuanha and tartar-emetic may be indifferently employed as an emetic? The answer is not difficult. In choosing between these emetic substances, we must be guided by the condition of the system, and the nature of the disease, as well as the intention for which the emetic is prescribed. In intermittents, if the frame of the patient be delicate, ipecacuanha is to be preferred; if it be robust, capable of bearing full vomiting with impunity, and without suffering from the subsequent debilitating effects of profuse sweating, the antimonial preparations will be found most useful. In continued fever, in selecting an emetic we must not only prefer that which will produce full vomiting, but which will excite also that state of the surface which may act as a crisis; consequently, the tartrate of antimony and potassa is preferable to ipecacuanha. The influence of nausea in checking hemorrhages has been well established; but the superiority of ipecacuanha over all other emetics in those connected with the uterus, has only lately been established by the experiments of M. Caffin,* and Dr. Osborne, of Dublin.† The latter found that in doses of a scruple taken in the evening, and followed by an acidulated saline purgative next morning, the

discharge in menorrhagia ceased in twenty-four hours; and when it returned after a short interval, the repetition, once or twice, of the ipecacuanha emetic never failed to render the cure permanent. Dr. Osborne's experiments were conducted in Sir P. Dun's Hospital: in several of the numerous cases treated in this manner, the ipecacuanha arrested the discharge after tartar-emetic had produced no beneficial effect: and its influence was not modified either by a full pulse, with much excitement, or in a greatly weakened state of the system. In dysentery the superiority of ipecacuanha, when full vomiting is required, was determined by a set of experiments made by Sir George Baker.* Finally, ipecacuanha is preferable in every instance in which the powers of the stomach require to be maintained, and yet vomiting is requisite; and in cases in which a chronic diarrhoea exists, there can be one opinion only as to its superiority over tartar-emetic.

Although the usual dose of ipecacuanha is from \mathfrak{z} i to $3\mathfrak{z}$, to promote full vomiting, yet this must vary considerably in reference to sex and temperament. The dose for a young infant is gr. i; for a child of from six to ten years of age grs. x; and for the youth of either sex under twenty from gr. xiv to \mathfrak{z} i.

With respect to the propriety of substituting emetina for ipecacuanha, some advantages might result from doing so; its effects, as an emetic for instance, are more certain, and its use is generally followed by sweating and a tendency to sleep. The dose of the emetina is small, not exceeding gr. v for an adult; and as it is very soluble in water, it can be more readily administered in divided doses than ipecacuanha. Besides, the powder of ipecacuanha loses much of its activity when kept for many months, whereas emetina is not at all altered by keeping.

6. *Squill, scilla maritima*.—The bulb of the squill, when properly dried, possesses considerable emetic powers, which are said to be attributed to a peculiar principle named *scillitina*;† but this is a compound substance, containing, besides the active principle of the squill, sugar, and traces of citrate of lime. Ether, when digested on squill, and evaporated afterwards on water, leaves on the surface a thin pellicle, intensely bitter, whilst a soluble matter mingles with the water: this pellicle is the real active principle of squill. Squill is seldom employed as an emetic; but in cases where its emetic influence is no objection and does not interfere with its expectorant powers, as in whooping-cough, croup, and some other pulmonary diseases, it is found useful. When

* Trans. of the Royal College of Physicians of London, vol. ii.

† Scillitina was first obtained from the squill by Vogel. When pure, it is colourless, intensely bitter, with some sweetness, friable, and resembles a resin in its appearance and fracture, and is equally soluble in water, alcohol, and vinegar. It is deliquescent, gives viscosity to water; but differs from gum in not affording mucic acid when it is treated with nitric acid.

* Journal Général de Médecine, vol. lxi.

† Observ. on the Employment of ipecac. in Menorrhagia.

emetics are thought to be serviceable in ascites and anasarca, squill has been supposed to be particularly indicated, but it is in no respect superior to tartar emetic in such cases. It is given in the form of powder, in doses of from grs. iii to gr. xii; or in that of tincture, from *m. xxx* to *f. ℥i*, repeated at intervals. When overdosed it operates as a narcotico-acrid poison, causing violent vomitings, diarrhoea, tormina, bloody urine, tetanus, and a cuticular eruption resembling urticaria: in some habits these effects result even after a small dose of the medicine.

7. *Tobacco*, *folia nicotianæ tabaci*, displays powerful emetic properties, whether it be taken into the stomach, inserted into the rectum, or applied to the surface of the body; but its operation is too difficult to controul to permit it to be prescribed, under any circumstances, as an emetic. It is mentioned merely because it has lately been recommended as a remedy in dropsy. In the event of its use producing poisonous effects, it is proper to know that infusion or tincture of galls renders the infusion of tobacco inert, and consequently should be instantly administered.

Inorganic emetics.—The first of these necessary to be noticed, is the *tartrate of antimony and potassa*, a salt which has been employed as an emetic since 1631.* As an emetic, it operates through the medium of the nerves, and probably never until it reaches the circulation. It proves emetic, or purgative, or sudorific, according to the frequency of the dose: thus a grain, dissolved in a moderate quantity of water, given every ten or fifteen minutes, produces full vomiting; the same quantity repeated every three hours may vomit once, but it afterwards purges; and if administered once in six hours only, it causes copious diaphoresis. It is the best of the emetic substances for producing full vomiting at the commencement of continued fevers, and in all cases where it is of advantage to keep up a state of nausea. In mania it is preferable to all other emetics; but it requires to be prescribed in much larger doses than in most other diseases, a scruple often producing little effect whilst the state of congestion of the brain remains; but, if the lancet have been previously resorted to, a grain or two grains will produce full vomiting. In melancholia the direct emetics are to be preferred, as the nausea which follows the use of tartar emetic is in this instance injurious, by augmenting the collapse which always occurs in this disease.

When overdosed, besides operating as a powerful emetic, tartar emetic produces poisonous effects on the mucous coat of the alimentary canal. The best antidotes are infusions of yellow cinchona bark, galls, catechu, or any of the astringent vegetables, the tannin of which unites with the oxide of antimony, and forms an insoluble inert salt. But it is not

easy to determine what is an overdose of this salt in disease. The custom of prescribing it in large doses has lately been revived by Rasori and other Italians, and their example has been much followed by all the continental physicians. Laennec states that he gave it to the extent of forty-eight grains, in divided doses, in twenty-four hours, without any deleterious effect, and even without exciting vomiting, except on the first day. Dr. Christie, in a treatise on the nature and treatment of cholera, asserts that he has given ℥i at once, with the effect only of producing some vomiting and a few watery stools. The writer of this article, who has frequently prescribed it in doses of grs. iii, repeated every third hour, has observed that it seldom causes vomiting after the second or third dose. Rasori explains the power of sustaining such large doses, on the principle that a peculiar diathesis accompanies diseases of excitement, in which only such doses can be borne; and that it ceases as recovery takes place. Laennec, however, says that this power of endurance does not cease at the close of the fever, although it is diminished; a circumstance which, if the observation be correct, may be ascribed to the force of habit.

When tartar emetic proves poisonous, the symptoms resemble those of cholera; violent vomiting, diarrhoea, great pain and tension of the abdomen, and delirium; convulsions supervene, and death sometimes results. These symptoms have sometimes followed the administration of moderate doses. On examination of the body after death, the only marks of previous excitement are slight congestion in the brain, and a thickened state of the villous coat of the stomach and the duodenum, which is covered with a tough mucus.

Tartar emetic is administered in substance, in solution in water, and in solution in wine. The latter preparation is an objectionable one; the free tartaric acid of the wine converting the potassa into a bitartrate, and thus decomposing the triple salt; and the solution should always be made at the time it is to be taken. The solution in wine is chiefly employed in the diseases of children. Some practitioners still adhere to the opinion of Sydenham, who reprobates the use of antimonial emetics for children under eight years of age; but we have never seen any disadvantage follow their administration to children of two or three years of age; nor even, when judiciously employed, to infants at the breast.

(A. T. Thomson.)

EMMENAGOGUES, (from *ἐμμήναι*, the menses, and *ἀγὰ*, to induce,) are medicines which promote the menstrual discharge. It has been doubted whether any medicines operate directly upon the uterus; the decided influence of some in promoting its periodical discharge being referred to the diseased organ sharing in the salutary effect of such medicines on the general system. To determine fairly the correctness of this opinion, we must take into consideration the nature of the organ and its function in the unimpregnated state.

* It was discovered prior to the above date, but was first made known by Adrian Mynsicht, in his treatise entitled, *Thesaurus Medico-Chemicus*.

The texture of the uterus is fibrous, dense, compact, and abounding in bloodvessels; the veins are destitute of valves: it is also well supplied with nerves, and with lymphatics on its external surface. Internally it is lined with a soft, delicate, spongy membrane, composed chiefly of capillary vessels. Such is the organ:—what is its function in the unimpregnated state? How far is it adapted to perform the functions of a secreting organ? Is the periodical evacuation derived from it a true secretion, or a mere discharge from vessels oppressed by a local plethora?

In reply to the first query, it is scarcely necessary to say that its function is menstruation; a discharge periodically recurring once a month. The second and third queries involve a matter of controversy; but the prevailing opinion is in favour of the capacity of the uterus to secrete; and, consequently, that the discharge which it exudes is a real secretion. There is nothing in the anatomical structure of the uterus that unfits it for the function of secretion; and were any arguments necessary to refute the notion that menstruation depends on a general plethoric orgasm, it would be only necessary to bring forward the curious facts bearing on this point presented by the Hungarian twin sisters. These two females were united at the lower part of the back, and lived to the age of twenty-two. The same blood flowed in the vessels of each,—for the abdominal vessels were found, after death, united at the loins; yet the uterine function was distinct in both; it differed in its period, and also in the quantity of the discharge. Indeed, in reflecting on the nature of the organ itself, on its resemblance to other glandular organs in the manner in which it is supplied with blood, and on the adaptation of its internal surface to exhalation, we can have little hesitation in admitting that the manner in which the periodical discharge is supplied closely resembles that of a secreted fluid. The uterine arteries are not only exceedingly convoluted, but they are larger and have thinner coats than the veins, in the unimpregnated state: the blood is, therefore, brought into the organ readily and in considerable quantity, whilst it is slowly returned from it,—a state of vessels highly favourable to the secreting function. It is true that, previously to menstruation taking place, there are symptoms indicative of general plethora as well as of local congestion; yet this fact only proves that the discharge is connected with such a state of the system; not that it is caused by this state, nor that the relief which follows is attributable to blood being discharged by the uterine vessels. The admission, also, that there is an increased determination of blood to the organ at the period of menstruation, does not militate against the opinion that the discharge is a secretion; since it is well known that every glandular organ, when excited by its appropriate stimulus, becomes a centre, as it were, to which the blood is directed. Again, if this discharge were merely the effect of a local plethora, it would be blood, which is not the fact; for it

does not coagulate like blood, nor does it contain fibrine. If it be thus evident from reasoning, that menstruation is not the mechanical result of a local congestion, let us examine how far observation supports the fact that it is a secretion.

The uterus, as we have already stated, resembles a gland in its vascular supply; and this resemblance extends to its diseases; an inflammatory state existing in it being often followed by scirrhous and cancer. Like other secreting organs, also, its function is often imperfectly performed, and the secretion, therefore, is liable to vitiation and derangement. In the first efforts of the organ the secretion is usually thin, colourless, defective in quantity, and its recurrence irregular and protracted: when it is suppressed, it cannot be restored by inducing plethora; nor can the flow, when it has commenced, be checked by venesection or any other means of depletion. In making this remark we must not be misunderstood: it is not our intention to assert that inordinate evacuations in other parts of the system do not influence the uterine discharge; on the contrary, we are perfectly aware that preternatural evacuations induced in the other organic systems will suspend the course of the catamenia, on the same principle that increased action of the intestinal system suspends the action of the cutaneous exhalents, and, *vice versa*, sweating checks diarrhoea. Any argument founded on the supposition that the structure of the uterus is not sufficiently glandular for a secreting organ must fall to the ground, when we reflect that the gastric juice is secreted by the stomach, an organ still less glandular than the uterus. We shall only add, that the correctness of the opinion that the catamenia are a secretion, does not depend altogether on circumstances connected with the organ itself; experience having ascertained that this discharge is intimately connected with the state of the ovaries; for when these organs are much diseased, or removed, or altogether absent, no menstruation occurs. It is not necessary to the establishment of the truth of our opinion that we should be able to explain the cause of the periodical return of the catamenia.

If menstruation depend, as we believe it does, on the secretory function of the uterus, it is obvious that in the unimpregnated state it ought always to happen at its regular period when the organ is in a natural or healthy state; and that in order to promote its return, when it is interrupted or suspended, such medicines must be employed as will tend to restore the organ to that precise state or condition on which the exercise of this function depends; and it is to these that the appellation *Emmenagogue* can only be properly applied. They may be such as will act either immediately on the uterus itself, or such as will merely influence that organ as a part of the general system; emmenagogues, therefore, may be arranged under two heads—*direct* and *indirect*. We shall be able to understand the manner in which both operate, and the propriety of employing the one or the other, only by having a clear idea of the

nature of the morbid condition of the organ, and whether the obstruction or interruption of the periodical discharge depend on a diseased state of the uterus itself, or is the effect of the presence of other diseases in the system.

In some instances the suppression of menstruation is a primary affection, "often," as Dr. Denman has justly remarked, "although not universally, succeeded by a certain train of untoward symptoms:" but more frequently it is the result of other diseases; and, therefore, the nature of these, as well as the state of the patient with respect to vigour and constitution of body, must determine the kind of remedial agents to be selected as emmenagogues. Thus when the delay of the regular appearance of the discharge, after it has once appeared, occurs in females with a pale or leucophlegmatic countenance, indicating an atony of the vital powers, stimulant and tonic medicines are required, to give to the vascular system that degree of power which is necessary to maintain the healthy action of the capillaries: on the contrary, when the complexion is florid, when there is much tension of the system, or when the suppression is connected with great irritation of the uterine system, it is easy to understand that menstruation is more likely to be aided by whatever can diminish excitement and sooth and calm irritation than by stimulants. Thence the fact, that very different, nay very opposite remedies are required to remove amenorrhœa, in different instances.

Stimulants, whether corporeal or mental, undoubtedly tend to an early development of the uterine organs, and consequently to the appearance of menstruation sooner than is usual: thus in tropical climates, and in those females who indulge in luxurious and pampered habits, the age of puberty is earlier than in those who inhabit the temperate and frigid zones, and whose habits and passions are better regulated. The continued influence of stimulants is said, also, to prolong menstruation beyond the period of life at which it usually ceases; but this is at least problematical. All emmenagogues are more or less stimulants; and in cases in which a stimulant influence is contra-indicated, they cannot be employed until the excitement be reduced, and can then be only employed under certain restrictions.

When the uterine obstruction or irregularity is accompanied with a *pale* complexion and a languid state of the system, a variety of medicines are prescribed, either with the view of directly influencing the uterus by some specific action, or of invigorating the habit, and thence eventually promoting its secretory function. By the indiscreet use of the former, much injury may be done to the organ itself: on the latter, however judiciously prescribed, we cannot always depend; they may improve greatly the general health, and yet the catamenia may not reappear. It ought also to be well understood that idiosyncrasy, natural conformation, diseased states of the uterus itself, or of the ovaries, often are obstacles effectually opposed to the salutary influence of emmenagogues. As we have already mentioned, it has been

doubted whether there is any medicinal agent which, when taken into the stomach, exerts a direct stimulant influence on the uterus: but if we admit that some substances find their way to particular organs,—for instance, nitre to the kidneys,—there is no reason why such should not be the case with regard to the uterus; experience, however, has not yet demonstrated that this is the case. But a stimulant effect may be propagated from neighbouring parts to the uterine vessels: thence some cathartics, which operate chiefly upon the rectum, influence the uterus.

When the obstruction is accompanied with a florid complexion, and "the colour of the cheeks is the flush of disease, not the glow of health,"* before taking into consideration the uterine function, bleeding and other antiphlogistic means of treatment must be resorted to; and until the general excitement be subdued, the employment of emmenagogues would be injurious. It is also questionable, whether, even after this has been accomplished, any of the substances supposed to act directly on the uterus should be employed; but if they may be administered, they will be most likely to prove beneficial when given immediately after the reduction of the febrile excitement.

The employment of emmenagogues is not confined to cases of simple obstruction or suppression. In some females the pain with which menstruation is accomplished embitters much of life. Some of the substances employed as emmenagogues are supposed directly to lessen uterine irritation; and thence they are closely allied with sedatives and antispasmodics.

I. *Direct* emmenagogues. These may be subdivided into *immediate* and *mediate*.

1. The only immediate emmenagogue is *electricity*. It is well known that when this powerful agent is passed through any part of the body, a painful sensation is felt at the point of communication. Thus, if the knob of a discharging rod, connected with a chain communicating with the outside of a charged Leyden jar, be applied to one side of the pelvis, and the knob of the jar itself be applied to the side, a feeling will be instantly produced, as if a small sword was thrust through the part, and a stimulant impulse is given to the uterus, by the direct passage of the electrical fluid through it. The stimulant influence of a shock thus communicated, is obvious by the sensation which it excites; but it equally takes place, though in less degree, when no sensation is produced, as when a continued current of the fluid is passed through the organ, by making it a part of a circuit communicating with the prime conductor of an electrical machine. The direct application of electricity is admissible only when a torpor of the uterus exists, indicated by a suppression of the catamenia with a pale complexion and a languid state of the circulation. But even in this state of the habit and the organ, it must be remembered that, whilst applied in moderation, this agent rouses the activity of torpid

* Denman.

parts, in large quantity it injures materially, if it do not destroy altogether the excitability of this organ. In employing electricity, therefore, as an emmenagogue, it should be first used under the form of accumulated electricity, or the bath as it is termed, then the aura, and, lastly, shocks should be given. At first, the shock should be moderate; as, in nervous habits, syncope has followed the unguarded communication of powerful shocks; but with ordinary caution in its application, electricity has been found a powerful agent in amenorrhœa depending either on general debility of the system or atony of the uterus itself. (See ELECTRICITY.)

The influence of ergot of rye, *secale cornutum*, on the impregnated uterus, at the period of parturition, has led to the belief that it may be employed as a direct emmenagogue. Admitting that ergot acts directly upon the uterus, it cannot be denied that its influence in parturition is opposed to that which is requisite for exciting the uterine discharge. If menstruation be a secretory action, a certain supply of blood is requisite for its performance; but ergot acting on the motor nerves, and causing muscular contraction, would necessarily lessen this supply, and produce a state of parts more calculated to impede than to forward the menstrual discharge. Experience has also demonstrated that ergot has indeed very slender pretensions to the character of an emmenagogue.

2. The mediate direct emmenagogues comprehend both organic and inorganic substances. Among the former, madder, the root of the *rubia tinctorum*, has been long employed and relied upon, without any accurate idea of the manner in which it operates; although, from its tinging the urine and the bones of a red colour, it has been supposed that, as it passes into the circulation, it finds its way to the uterus, and directly influences that organ. The late Dr. Barton, an American physician of eminence, placed great reliance on its deobstruent powers; and it was also much esteemed by the late Dr. Home, of Edinburgh, who, in his clinical experiments and histories, has recorded his decided opinion of its efficacy as an emmenagogue. He gave it in doses of from 3ʒ to 3i. twice or three times a day. But notwithstanding these authorities, madder is an equivocal emmenagogue, and is now rarely or never employed.

Savine, the leaves and herbaceous part of the *juniperus sabina*, which owes its stimulant properties to a volatile oil having some affinity to that of turpentine, is an energetic emmenagogue; and from its proneness to produce uterine hemorrhage, and cause abortion, there is some reason for the opinion that the volatile oil is taken into the circulation and acts directly upon the uterus, on which it exerts a stimulant influence. More than a century ago, its tendency to produce abortion led to its employment as an emmenagogue; but from an opinion expressed by Dr. Cullen, it fell into disrepute. In whatever manner it acts, *savine*, or its oil, is well adapted for cases of

amenorrhœa connected with a feeble state of the constitution, and a languid circulation. The dose of the powder is from gr. v. to gr. x.; that of the oil, which can be readily formed into an oleo-saccharum, from m. ii. to m. vi. The extract, ordered by the Dublin Pharmacopœia, is a useless preparation; the volatile oil being dissipated by the heat necessary to be used in forming the extract.

Seneka root, the root of the *polygala senega*, is esteemed a useful and active emmenagogue by the American physicians. The active principle, which is supposed to be a peculiar salt, first noticed by Peschier, and named by him polygaline or polygalina,* resides in the bark of the root. Dr. Hartshorne, of Philadelphia, who first employed it as an emmenagogue, found that it was most useful in recent cases of amenorrhœa. He began its use two weeks previous to the expected appearance of the catamenia, giving it in the form of a saturated decoction, to the extent of a pint in twenty-four hours, pushing the dose as far as the stomach would permit, until the discharge appeared. Dr. Chapman, of Pennsylvania, adds his testimony to that of Dr. Hartshorne in favour of *senega* root, and believes that it exerts a specific action on the uterus; but it ought to be mentioned that the patient is directed to be prepared by an alterative course of calomel, carried to gentle ptyalism; on which account it is difficult to say how much is due to the mercurial, how much to the *senega*. If, however, the observations of the American physicians be correct, *polygala senega* merits the attention of British practitioners as an emmenagogue.

No medicines perhaps merit more the appellation of direct mediate emmenagogues than the preparations of *mercury*. They effect almost a specific change upon the whole glandular system; and, consequently, if the glandular nature of the uterine function be admitted, it is easy to conceive that they are likely to affect the capillaries in the uterus, when these are in an unnatural or morbid condition. The preparation best suited for emmenagogue purposes is calomel; it is mild in its operation, and at the same time certain in its influence on the general system. In the combination in which it exists in Plummer's pill in particular, it has been found highly beneficial, the precipitated sulphuret of antimony greatly aiding its power. In this combination, it may be given in doses of from five to twelve grains every night and morning, until the gums be sensibly affected.

From what has been said, it is obvious that electricity is the only direct emmenagogue, and that the idea of the others acting upon the uterus itself is rather inferred than certain. It is nevertheless true, that, in whatever manner they act, they stimulate the uterus; and, therefore, some caution is requisite to be ob-

* Peschier procured gr. 100 of this salt from ʒvi. of the root. He asserts that it is united with a peculiar acid, which he has called *polygalinic*.

served in their administration. Thus we must be certain that the suppression is not connected with pregnancy; and even, when this is not the case, there is some difficulty in deciding upon the propriety of administering direct and stimulant emmenagogues; the uterus may be in such a state of active disease, as to render their influence upon it extremely hazardous.

II. *Indirect* emmenagogues. The operation of these is effected in three ways:

1. By the substance operating on the kidneys or the intestinal canal, and stimulating the uterus by proximity.

2. By the substance acting on the stomach and improving the general health, so that the uterus shares the general salutary influence.

3. The uterus may be specifically acted upon through the medium of the nervous system.

The substances that operate in the first manner are, some diuretics, and those cathartics which especially stimulate the rectum. The diuretics are such as pass to the kidneys undecomposed, and powerfully stimulate these organs: thus nitre administered in doses of from $\mathfrak{z}i.$ to $\mathfrak{z}i.$, in any bland fluid, possesses decided emmenagogue powers. Foxglove operates in the same manner. Among the emmenagogue cathartics, aloes holds the first rank. Its influence can only be referred to its action on the rectum, and its extension to the uterus, producing a state of the organ closely allied to that which is the result of the application of a direct stimulus to it. The powerful sympathetic influence of aloetics is well illustrated by the effect which sometimes follows their administration after the total cessation of the catamenia. For a certain period after this event takes place, the uterus retains the disposition to take on that state of vascular action which determines the periodical discharge; but it is incapable by its natural efforts to effect the discharge. In this state of uterine susceptibility, the excitement of the rectum by an aloetic purgative almost invariably induces the return of the menses in a slight degree, provided the cathartic be given at the period when the discharge had previously been accustomed to appear. Now if a purgative produce so powerful a sympathetic action when this uterine function has ceased to be any longer essential, we can readily imagine that a more powerful effect is likely to be the result of a similar extension of action from the rectum to the uterus at a period of life when the susceptibility to uterine impressions exists in a high degree. Experience has sufficiently demonstrated that such an extension of action really occurs. In prescribing aloes, however, as an emmenagogue, the cause of the suppression must be kept in view; for this medicine cannot be safely administered in an irritable state of the uterus. To secure its influence on the uterus, it is supposed necessary to administer the medicine in a solid form; but we are of opinion that this supposition is founded on a mistaken idea of its mode of acting; we have seen it

most successful when it has been prescribed in conjunction with alkalies, which greatly aid its solubility. The administration of a pill containing one grain of calomel, the same quantity of powder of digitalis, and three of extract of conium, at bed-time, followed in the morning, by half an ounce of wine of aloes and myrrh, in conjunction with the mineral alkalies and ammonia,* for two or three days previous to the expected return of the menstrual discharge, have, in our hands, proved generally successful. We are usually advised to avoid recommending the use of aloetics to persons subject to hemorrhoids; but although they operate chiefly on the large intestines, the idea that they produce hemorrhoids, or even rouse them to activity in those affected by them, unless the dose be very large, is doubtful.

Black hellebore, *radix hellebori nigri*, is another useful emmenagogue purgative of this class, adapted to plethoric habits: it probably acts by reducing that state of the system which is as adverse to the secretory action of every glandular organ as to that of the uterus. Mead pronounced a high eulogy on the emmenagogue properties of black hellebore; and it continued to be much employed until doubts of its efficacy were raised by Cullen and Heberden,† after which it fell into disrepute; but it is still much prescribed on the continent of Europe and in the United States of America. Dr. Chapman thus expresses himself regarding it: "it is especially useful when it purges, in painful menstruation, attended with torpor and constipation of the bowels, and perhaps with some degree of insensibility in the uterus itself."‡ From the violence of its action as a purgative, black hellebore requires to be administered with caution. If it be employed, the tincture is the best form of preparation; it may be added to any purgative, and thus aid in stimulating the uterus with less risk than is likely to attend the use of the root in substance or its infusion. The extract of the Edinburgh Pharmacopœia, in doses of from gr. iv. to gr. x., combined with extract of conium, has been found useful in the amenorrhœa of chlorotic girls. The same remarks apply to camboge. *Serpentaria*, *valerian*, and *wormwood*, have been employed, in various combinations, to produce emmenagogue effects, and seem to operate chiefly as stimulant antispasmodics. As such, the preparation of valerian, particularly the ammoniated tincture, is indicated in hysterical habits, when the circulation is in a languid state, and the menstrual discharge ushered in with an hysterical paroxysm: it seems to act chiefly by soothing the nervous turbulence; and may be given in doses of from $f\mathfrak{z}i.$ to $f\mathfrak{z}i.$ in combination with decoction of aloes.

* See London Dispensatory, sixth edit. p. 941.

‡ *Materia Medica.*

The inorganic substances in this division of emmenagogues are, principally, salts of iron, both natural and artificial. The former, which, as they exist in chalybeate waters, are carbonates or sulphates, are most beneficial when drunk at the springs; they raise the pulse in strength, and distribute the blood more equally; and, although the quantity of iron contained in the dose of the water, generally half a pint, be extremely small, yet it operates as a decided stimulant tonic. In plethoric individuals, it is often requisite to bleed and purge before the use of the chalybeate is commenced; and if nausea, pain of the præcordia, vomiting, vertigo, or a feeling of general fullness be, nevertheless, experienced after the waters have been taken, they should immediately be discontinued. All the varieties of chalybeate water prove beneficial in amenorrhœa connected with a pale leucophlegmatic habit; their operation is on the secretory system, which they influence in a slow but uniformly progressive manner, imparting tone, nervous energy, and general vigour. When the habit of the patient is sluggish, the pilula aloes cum myrrha may be administered with each dose of the water. The whole quantity of the chalybeate necessary to be taken in one day should be drunk in divided doses, betwixt each of which brisk walking exercise should be used. The artificial preparations require to be given in much larger doses than those contained in the chalybeate waters, a circumstance which has not been satisfactorily explained. The most common of the artificial preparations employed in amenorrhœa is the official *black oxide* of iron, the scales from the anvil purified. It is a compound of the protoxide and peroxide; the former of which combines readily with the acid of the stomach. The dose is from gr. v. to ℥i.; it may be combined with an aromatic, and administered two or three times a day. Neither the liquor ferri alkalini, nor the ferrum ammoniatum, are active preparations: perhaps the most energetic of all the artificial chalybeates is the tincture of muriated iron; and it possesses the advantage of being compatible with many bitter tonic infusions and decoctions; as, for example, those of gentian, quassia, orange-peel, and such like. If the sulphate of iron be preferred, it should always be in the form of the proto-sulphate; but as this salt is rapidly converted into the persulphate when it is kept in the usual manner, it should be preserved in alcohol.* In the formation, also, of the *mistura ferri composita*, it would be preferable to add the sulphate of iron, in solution, to the mixture of myrrh and subcarbonate of potassa at the moment of taking the medicine, than to prepare it as ordered in the London and Dublin Pharmacopœia. When previously mixed, the car-

bonate of iron, which is at first formed by the exchange of acids between the salt of iron and the alkaline carbonate, is again rapidly decomposed, and transmuted into an inert peroxide of iron; whereas, when managed as we propose, the protocarbonate is formed in the stomach, and immediately exerts its influence upon it, operating as a powerful and effectual tonic emmenagogue. The dose of the protosulphate proper to mix with $\frac{1}{3}$ ℥i. of the myrrh and alkaline solution, is four grains. Its influence is perceived by the rapid change which it induces on the alvine and renal evacuations; the black colour of the former, and the blue streak when the latter is tested with ferrocyanate of potassa, demonstrating that the chalybeate has entered the circulation.

The mediate indirect emmenagogues which influence the uterine function by their action on the nervous system, are all organic substances, both animal and vegetable. Their influence is chiefly useful when amenorrhœa accompanies highly irritable habits, and the suppression is connected with spasm and hysteria. We are of opinion that much confidence cannot be given to *castor* or to *musk*; galbanum and assafetida are more useful; but they are to be regarded merely as aids to more powerful indirect emmenagogues.

On reviewing what has been said on this subject, it is evident that, with the exception of electricity, there is no method of directly stimulating the uterus on which much confidence can be placed; for little benefit has hitherto been derived from stimulating injections; and under these circumstances it may be reasonably questioned whether any medicinal agent can be correctly entitled to the appellation *emmenagogue*.

(A. T. Thomson.)

EMPHYSEMA.—This term, derived from the Greek verb *ἐμφυσάω*, to inflate, is used in medical language to signify the presence of air in the cellular tissue.

The portion of the cellular tissue which is most frequently affected with emphysema is the subcutaneous; but as all the prolongations of this tissue throughout the body are directly continuous, and communicate freely by their areolar structure, the air in emphysema, when once effused in any part of it, may extend wherever cellular tissue exists.

Frank remarks that thin persons are more liable to emphysema than those whose cellular tissue is loaded with fat; and it is matter of common observation, that those parts of the body where the cellular tissue is lax and free from fat are most easily affected with this disease. Thus, the eyelids, scrotum, neck, and sides of the thorax, yield readily to the admission of air, while the buttocks and thighs, the arms and legs are much more slowly distended. The dense cellular tissue which lines the serous and mucous membranes yields with still more difficulty to emphysema, and the palms of the hands and soles of the feet are among the last parts to become so affected.

There are two modes in which emphysema

* Green vitriol consists of 36 parts of protoxide of iron, + 40 of sulphuric acid, + 63 of water of crystallization, = 139: when exposed to the air, oxygen is absorbed, and an insoluble subsulphate produced, which consists of 40 parts of acid, + 160 peroxide of iron, = 200.

may be produced: 1. by the introduction of atmospheric air into the cellular tissue, through a solution of its continuity; or, 2. by the development of gas within the cells of the part. The former is termed *traumatic*, the latter *idiopathic* or *spontaneous* emphysema.

Traumatic emphysema is of much more frequent occurrence than the idiopathic species. It may succeed to any wound of the integuments which allows the external air to get into the subjacent cellular tissue; but in a great majority of cases, (amounting to ninety-nine out of the hundred,) it arises from the introduction of air into the common cellular tissue through a communication formed more or less directly with the organs of respiration. The following are the principal ways in which this communication may be established. 1. By wounds or ulcers communicating with the interior of the mouth or nares. 2. By perforation of the larynx or trachea. 3. By rupture of the air-cells and interlobular cellular tissue, the investing membrane or pleura remaining uninjured, and the air escaping through the roots of the lungs and mediastinum into the general cellular tissue. 4. By perforation of the lung, pleura pulmonalis, and pleura costalis. 5. By penetrating wounds of the chest, the lung and its investing membrane remaining uninjured.

1. Wounds or ulcers communicating with the interior of the mouth or nares.—Frank states that emphysema is not unfrequently produced in persons learning to play on the flute, or other wind instruments, in consequence of the air being forced into the parietes of the cheek through any wound or small ulcer which may happen to exist on its internal surface.* And M. Rullier informs us that the prisoners in the Bicêtre at Paris, when they wished to be transferred to the infirmary, were in the habit of producing an artificial emphysema of the face and throat, by puncturing the inside of the cheek with a pin, and then forcing the breath through the puncture.† In wounds of the under-eyelid communicating with the lachrymal sac, emphysema is not a very uncommon occurrence, the air passing from the nares, through the duct, into the sac, and thence finding its way into the lax cellular tissue in the neighbourhood: in like manner emphysema of the head and face has been observed to take place in cases of fracture of the frontal bone communicating with the interior of the nares.

2. Perforation of the larynx or trachea.—In wounds of the larynx or trachea, part of the air which is expelled from the lungs at each expiration, instead of passing through the glottis, escapes through the wound; but if its free exit is opposed by the narrowness or obliquity of the external orifice, instead of passing out directly, it insinuates itself into the areolæ of the cellular tissue, forming an emphysematous swelling round the wound, and from thence extending all over the body. Instances have also occurred, where, from a severe blow, some of the rings of the trachea

have been ruptured; and the same effect has been said to arise from coughing. We are not acquainted with the records of any case in which perforating ulcers of the larynx or trachea have led to the formation of emphysema; a fact which is probably to be accounted for by the air being prevented from entering the cellular tissue by the adhesive inflammation which usually precedes and limits the ulcerative process.

3. Rupture of the air-cells and interlobular cellular tissue, the investing membrane or pleura remaining uninjured, and the air escaping through the roots of the lung and mediastinum into the general cellular tissue. The rupture of the parietes of the air-cells formed by the ultimate ramifications of the bronchi is by no means an uncommon occurrence; (see EMPHYSEMA OF THE LUNGS;) but so long as the cellular tissue which invests each lobule, and isolates it from those adjoining, remains uninjured, the extravasated air is prevented from escaping beyond the lobule in which the ruptured air-cells are situated. When, however, the cellular tissue which invests each lobule, and which is in fact a prolongation or process of the general cellular tissue, of the body, is likewise lacerated, the air is then at liberty to enter the cells of that tissue which communicate one with another throughout the lung, and through the root of the lung and mediastinum, with the cellular tissue of the throat; so that having once found its way from the ruptured air-cells into the interlobular cellular tissue, it passes uninterruptedly from cell to cell, (when urged forward by a sufficient force,) until it reaches the cellular tissue of the throat, where it makes its appearance in the form of an elastic crepitating tumour over one or both clavicles, and soon becomes diffused over the face and trunk.

This variety of emphysema may be produced by violent fits of straining, coughing, or crying, or any other exertion of the respiratory organs, sufficiently powerful to rupture the air-cells and interlobular cellular tissue; but it has been observed to occur most frequently in women during parturition, and in children severely affected with the whooping-cough. Dr. A. Hamilton, of Edinburgh, observed a case of emphysema produced in this way by the efforts which a young woman made to conceal the pains of labour. She suddenly lost her voice, and her face became swelled in a wonderful manner; her respiration, too, became quick and laborious, and her pulse full and rapid. However, by rubbing the tumid parts twice in the day with camphorated oil, and taking away a considerable quantity of blood from the arm, together with the use of laxative medicines, and an opiate at bed-time, the swelling began to give way in the course of a week; and in proportion as the emphysema disappeared, she recovered her voice. (Halliday on Emphysema.)

Dr. Johnson, the learned professor of Midwifery in the Royal College of Surgeons of Dublin, informs us that six cases of this

* De curand. hom. morbis: Art. Pneumatosis.

† Dict. de Médecine, Art. Emphysème.

accident have occurred in his practice. In general the emphysematous swelling is confined to the neighbourhood of the throat, where it first makes its appearance; but in some cases it extends with a frightful rapidity, and involves the entire surface of the body. In one case it extended to the very tips of the fingers. This form of emphysema is likewise occasionally produced by violent paroxysms of the whooping-cough. Dr. Johnson has known it occur in three cases of this disease; and Dr. Mackintosh of Edinburgh, and the late Dr. Beattie of Dublin, mentioned to us similar cases that had fallen under their observation. An interesting case of this form of emphysema is also recorded by Dr. Ireland, in the third volume of the Dublin Transactions.—“A child nine years old was attacked with pneumonia. Under appropriate treatment the inflammatory symptoms seemed to subside, but a severe cough remained behind, during a violent fit of which a colourless crepitating swelling was observed to form above the clavicles, and extended rapidly until it spread over the whole body. The child died, apparently of suffocation, on the fifth day after the appearance of the emphysema.” A case of emphysema of this kind is related by Louis,* which was produced by the efforts made to expel a bean that had fallen into the larynx. We have, however, had opportunities of observing that a fatal suffocation may be caused by the presence of a foreign body in the air-tubes, without necessarily producing this symptom.

It is probable that many cases of emphysema supposed to be spontaneous are really produced in this manner. Thus, the emphysema which sometimes appears on the sides of the thorax when much force is employed to reduce a dislocation of the humerus, probably arises from the escape of air in the manner we have described, through a rupture of the air-cells caused by the violent efforts which the patient makes to hold in his breath during the reduction of the dislocation. In like manner the emphysematous swellings which have been noticed by Frank, Cullen, and other practical writers, as occasionally occurring during the paroxysms of hysteria, may proceed from the air being forced through the cellular tissue of the lung and mediastinum, by the violent efforts at expiration which are made during the paroxysm, while the aperture of the glottis is kept spasmodically constricted.

The great difficulty of breathing which occurs in this form of emphysema is sufficiently accounted for by the distention of the lung, from the infiltration of its interlobular tissue with air, and by the emphysematous swelling of the mediastinum.

4. Perforation of the lung, *pleura pulmonalis*, and *pleura costalis*. This triple lesion may be produced—1. by fracture of the ribs; 2. by penetrating wounds of the chest and lungs; 3. by ulceration. As the emphysema which arises from the first two of these causes belongs more particularly to the province of surgery,

we shall notice it very briefly, and refer the reader, who wishes for further details, to the works of surgical writers.

There is no accident which so frequently gives rise to emphysema as fracture of the ribs; for when the sharp ends of the fractured bones protrude through the *pleuræ* and lacerate the *parenchyma* of the lung, the air passes freely through the bronchi into the sac of the *pleura*, and thence through the breach in the costal *pleura* into the subcutaneous cellular tissue, from whence it becomes diffused all over the body, as there is no opening in the integuments through which it can escape externally. At each dilatation of the chest the air is sucked into the thorax through the lacerated air-cells, and diffused uniformly over the surface of the lung, (supposing that no adhesions exist,) while at each effort of expiration the stratum of air contained within the *pleura*, being compressed by the contraction of the thoracic *parietes* against the entire pulmonary surface, is prevented returning by the wound through which it had previously entered; in this way the air continues to accumulate within the sac of the *pleura*, until it becomes so condensed, especially during the efforts of expiration, as to exert a very considerable degree of pressure on the *parietes* of the chest, and the important organs contained within it. The air then forces its way through the breach in the costal *pleura* made by the protrusion of the fractured bone, and escapes into the cellular tissue on the outside of the thorax, whence it is rapidly diffused all over the body, a fresh supply of air being forced out at each expiration, so long as the wound in the lung continues permeable.

From this view of the mechanism by which emphysema is produced in the case of a fractured rib, it is evident that the escape of air into the cellular tissue, which has commonly been looked upon as the most dangerous part of the disease, should with more propriety be regarded as a favourable circumstance, inasmuch as the air which escapes in this way would, if confined within the *pleura*, oppress not only the lung of that side where it is contained, but, by hindering the play of the diaphragm, and thrusting the mediastinum over into the opposite side, oppress the other lung also, and so produce great difficulty of breathing, or even a fatal suffocation.

In the greater number of cases of emphysema arising from fracture of the ribs, the wound of the lung is soon closed by the effusion of blood, or by adhesive inflammation; after which the further escape of air into the *pleura* ceases; that already effused is promptly absorbed; the respiration is no longer laborious; the subcutaneous emphysema ceases to extend, and in the course of a few days is removed by absorption.

But in more severe cases the wound of the lung remains unclosed, and a fresh supply of air is pumped into the cellular tissue at each expiration, until the whole body becomes so distended as scarcely to retain a semblance of the human form. The following “History of an Emphysema,” from the pen of Dr. William

* Mém. de l'Acad. de Chir. t. iv.

Hunter, is exceedingly characteristic of the appearances produced by excessive distention of the subcutaneous cellular tissue, and of the peculiar difficulty of breathing caused by the pressure of the air accumulated within the sac of the pleura:—"The patient had received a considerable hurt in his side by a fall from his horse. When first seen by Dr. Hunter (twenty-nine hours after the accident), he was in bed, panting for breath; his form was that of a human skin stuffed. The inflation was great and universal, except in his hands and feet, where it was very inconsiderable. The skin was everywhere shining, as it is when much extended by any kind of swelling. The air could easily be pressed out from any part, but it immediately returned upon taking off the hand. When struck, his body sounded like a wet drum; and when pressed, the air could be felt, and its sound distinctly heard. The cellular membrane was less inflated, and the skin less distended upon his extremities, in proportion nearly to the distance of the part from his chest. Those parts on the surface of the body which have a more loose and yielding cellular membrane were proportionably more swelled; thence his eyelids were so fixed by their own bulk that he had not been able to see light from a few hours after the accident happened. The penis and scrotum were as much distended as in the worst anasarca."

It is impossible to convey a more accurate description of the appearance which this disease presents in its most aggravated form. Dr. Hunter's description of the difficulty of breathing produced by the air accumulated within the sac of the pleura, is equally characteristic: "His breathing was very laborious, and rather frequent, in the following manner:—his inspiration was so short as to be almost instantaneous, and ended with that catch in the throat which is produced by shutting the glottis; after this he strained to expire without any noise; then suddenly opening the glottis, he forced out his breath with a sort of inward groan, and in a hurry, and then quickly inspired again; so that his endeavour seemed to be to keep his lungs always full. Inspiration succeeded expiration as fast as possible. From the small quantity that was inspired and expired at a time, it was plain that he either had not room for a greater quantity, or could not bear a greater expansion of the chest."*

When the surface of the lung is attached by adhesions to the costal pleura, the air which escapes from the wounded lung cannot accumulate within the chest, but passes directly through the corresponding wound of the costal pleura into the cellular tissue on the outside of the thorax; in which case there is no pneumothorax, and the difficulty of breathing is consequently much less.

Emphysema may likewise be produced in this way by penetrating wounds of the chest and lungs. It has, however, been observed that these wounds are not as constantly followed by emphysema as fracture of the ribs is.

The mechanism by which the emphysema is produced is the same in both cases, the air first escaping through the wounded lung into the sac of the pleura, and thence through the wound of the costal pleura into the subcutaneous cellular tissue. When the wound of the integuments is large, and directly parallel to its internal orifice, the air has an open and unobstructed issue, through which it passes; but when the external wound is narrower than its internal orifice, or only communicates with it obliquely, the air which is forced out may then insinuate itself into the areolæ of the cellular tissue, and thus produce emphysema.

Mr. Hewson endeavoured to produce artificial emphysema by cutting and wounding the lungs of rabbits and dogs in various ways; but all his experiments were unsuccessful: no air was effused either into the cavity of the thorax, or into the cellular membrane. From these experiments he concluded that a puncture or incision of the lungs would seldom produce emphysema, on account of the effusion of blood from the divided vessels, and that the escape of air is more apt to follow a superficial abrasion or laceration of the part, such as is produced by the extremity of a fractured rib; and experience has fully confirmed the accuracy of these conclusions.*

M. Litre has published a case of emphysema produced by the thrust of a small sword, which is remarkable on account of the enormous distention of the cellular tissue that took place. The emphysema commenced soon after the accident, and the patient died in two days. On examination after death, the emphysematous swelling on the chest measured eleven inches thick, on the belly nine, on the neck six, and four on the other parts of the body; the wound in the lungs was seven or eight lines long, one and a half broad, and one deep.†

Ulceration of the lung, pleura pulmonalis, and pleura costalis, is the last mode we have enumerated in which a communication may be formed between the interior of the lung and the cellular tissue on the trunk. In some cases a direct communication is thus formed, as when a circumscribed empyema that points externally between the ribs, or an abscess primarily formed in the parietes of the chest, bursts internally into the bronchi, and thus forms a direct communication between the air-passages and the abscess on the thorax. In such cases the pus is evacuated by the bronchi, and its place is supplied with air, which may either infiltrate the cellular tissue of the trunk, producing general emphysema, or, if the walls of the abscess have been rendered impermeable by adhesive inflammation, may be prevented from escaping further, and thus produce a circumscribed emphysematous tumour, bearing the same relation to diffuse emphysema that phlegmonous abscess does to common cellular inflammation. A remarkable case of this kind,

* See Hennen's Principles of Military Surgery, J. Bell on Wounds, and Baron Larrey's Mémoires de Chir. Militaire.

† Mém. de l'Académie Royale des Sciences, for 1713.

* Med. Obs. and Inquiries, vol. ii.

in which several emphysematous tumours were formed in succession over the surface of the chest and neck, is recorded by Dr. Duncan, in the first volume of the *Medico-Chirurgical Transactions of Edinburgh*.

This communication may likewise take place indirectly, the air first escaping through an ulcer on the surface of the lungs into the sac of the pleura, producing pneumothorax, and thence, through an ulcer of the costal pleura, into the cellular tissue of the trunk. A remarkable instance of this kind is related by Dr. Halliday. The patient had felt unwell for some days, and on the evening before his admission into hospital was seized with rigors and severe headach; he had also a slight cough, which excited some pain about the superior part of the sternum. Early the next morning he began to complain of great difficulty in respiring; at twelve o'clock the breathing had become more severe, his face was turgid, and his lips quite livid; there was also at this time an unusual fulness of the neck and breast, which, when pressed, yielded an evident crackling noise. In about half an hour after, this fulness was become not only more evident, but was diffused all over the chest, and down both arms; he had now the greatest difficulty in respiring at all, and before one o'clock every part of the surface of his body was become emphysematous, except the palms of his hands and the soles of his feet. On inspection after death, the right lung was found to contain, in its upper lobe, a vomica of about three inches in circumference, from which it appeared that about four ounces of pus had very lately escaped into the sac of the pleura, through an opening which would scarcely admit the head of a probe: upon blowing into the trachea it was observed that the air passed freely through this opening into the sac of the pleura. On searching for the opening through which the air had escaped from the cavity of the thorax, a small part of the pleura costalis, between the sixth and eighth ribs, was discovered with the appearance of being more inflamed than any other part; and nearly in the centre of this small spot an opening was detected, through which the pleura and cellular membrane were easily inflated.*

5. Emphysema may likewise be produced by penetrating wounds of the chest, even though the lung and pulmonary pleura remain uninjured. The formation of emphysema in such cases may be explained as follows. In all wounds of the chest where the air is admitted into contact with the pulmonary pleura, the lung generally collapses, when not prevented from so doing by emphysema of its tissue, or by old adhesions: a sort of false respiration is then established, air being inspired into the chest through the wound at each dilatation of the thorax, and alternately expired through the same orifice at each contraction of the thoracic parietes. But when, as not unfrequently happens, the wound remains direct and unobstructed during inspi-

ration, but becomes oblique or even closed by the alteration in the relative position of the integuments and ribs during expiration, it follows that the air having a free ingress into the thorax during inspiration, and not having as free an egress during expiration, must suffer such a degree of pressure from the contraction of the chest as to be forced into the subcutaneous tissue, and so produce general emphysema.

The last variety of traumatic emphysema we shall notice is that produced by the escape of air from the alimentary canal, through a rupture of its parietes. It appears from an interesting work, published by M.M. Chabert and Huzard, entitled, "*Observations sur les Animaux Domestiques*," that this accident is not of unfrequent occurrence in ruminating animals, in consequence of their food fermenting and generating such a quantity of gas as ruptures the internal tunic of the intestines, insinuates itself into the subserous cellular tissue, and thence extends all over the body. Haller mentions a case of emphysema produced in this way in a female, whose intestines were so over-distended by the quantity of gas they contained, that they at last gave way and allowed the air to escape into the cellular tissue.*

In the eleventh volume of the *Archives G n rales de M decine* there is a very interesting case of an extensive emphysema produced in this way by a violent contusion on the abdomen.

We have now enumerated the principal varieties of *traumatic* emphysema, and described the mechanism of their formation; but we have yet to consider another form of this disease, in which the air is not introduced from without, but is formed within the cellular tissue of the part, and which, as arising from no very evident cause, has received the denomination of *idiopathic* or *spontaneous*.

The air or gaseous product which is formed in spontaneous emphysema may be produced either by putrefactive decomposition or by secretion.

1. Spontaneous emphysema caused by the extrication of gas from a putrefactive decomposition. The living body is composed of various elements, which are only prevented from decomposing and entering into new combinations by the powers of life, which, by a counteracting influence, prevent the chemical affinities of these elements from coming into full operation; but no sooner do those powers cease to act, than the body begins to decompose under the influence of the chemical and physical laws which govern all inert matter. One of the most constant phenomena of this putrefactive decomposition is the disengagement of various gases; hence it is that dead bodies become emphysematous during putrefaction, and that the bodies of drowned men are after some days buoyed up and float on the surface of the water.

The extrication of gas from the death and decomposition of a part may likewise occur

* Op. Cit.

* Opusc. Pathol. Obs. xxxi. tom. iii.

during life, as in the case of gangrene. Indeed this is by no means a rare occurrence, particularly when the gangrene is of the humid species. "I took particular notice (says Dr. Hunter) of the emphysema in a case of mortification from an internal cause, which began upon the ankle, and thence marched upwards upon the limb till it came to the groin, when the patient died. The cellular membrane under the skin was very sensibly inflated every where, to some distance from the mortified part, and I could as easily mark the progress of the mortification from day to day by the emphysema as by the change of colour in the integuments."* Practical writers have remarked that gangrene, when accompanied with emphysema, has a remarkable disposition to spread.†

The period at which the putrefactive decomposition commences after death depends in a great measure on external circumstances, such as heat, moisture, &c.; but it is also materially influenced by the condition of the fluids, which in some cases have a much greater tendency to putrescency than in others; as is proved by the well-known fact that some bodies will remain for several days without exhibiting any sign of decomposition, while others from the state of the fluids swell up and run into putrefaction immediately after death. In the typhous fever that raged in the south of Ireland during the year 1817, it was found necessary to bury the bodies of those that died within a few hours after death, and to fill up the graves with lime.

The same tendency to putrescence is sometimes observed during *life*, in certain morbid conditions of the economy, which have hence obtained the name of *putrid* or *malignant diseases*. We know, from direct experiment, that the introduction of certain deleterious substances into the blood, such as pus, putrid animal matter, and certain poisons from the animal, vegetable, or mineral kingdom, produces certain alterations in it, by which it loses its power of coagulating, and acquires a tendency to rapid decomposition. Similar alterations are likewise produced in the blood by the sting or bite of certain animals, especially those of the serpent tribe; and are also observed in the spasmodic cholera, the plague, and other diseases of a malignant nature, as it is termed; in all which some of the most constant phenomena are a sudden prostration of strength, a constant tendency to hemorrhage, and a remarkable disposition to mortification wherever congestions are formed.‡ In such cases the *vis vite* is actually diminished throughout the whole system, and the laws which govern all inorganic matter begin to exert their influence over the body while yet alive, producing, amongst other symptoms of decomposition, spontaneous emphysema.

"A full-bodied middle-aged sailor was seized with a putrid fever and sore throat; he was bled at the beginning, but his blood

appearing in a loose dissolving state, he was bled no more: about the seventh or eighth day of his disease, an emphysematous swelling appeared in his face, neck, and all over his breast, especially on the right side; the swelling was fomented with sharp vinegar and camphorated spirit of wine, and under this treatment totally vanished in two or three days, and he soon recovered from the fever; but he continued very weak for a long time, and remained very scorbutic as he was before the fever, his gums being very spongy and bleeding on the slightest touch. In this case the emphysema was generated merely by the putrescence of the humours, as is frequently observed in a less degree in and about the incipient gangrene of the limbs; and I am persuaded that this more frequently happens in putrid malignant fevers than is commonly imagined."*

Frank states that the epidemic fever which raged at Bobbio, a small town in Italy, in 1789, frequently terminated in general emphysema; and that a similar epidemic had previously occurred in Germany in 1772, during which emphysematous swellings suddenly appeared on the face and neck, and sometimes extended all over the body.†

Neither is this development of gas from the decomposition of the fluids peculiar to man. Dr. William Hunter has transmitted to us the history of an epidemical distemper prevalent among the black cattle in the neighbourhood of London, in which it was observed. At first, almost all died that were taken ill of it; most of the diseased were emphysematous all over their body; and on dissection the emphysema was found to be universal upon all the internal parts, as well as under the skin.‡ Frank likewise alludes to an epidemic dysentery among the black cattle, during the progress of which the loins and back were frequently observed to become emphysematous.

The last illustration which we shall adduce is one lately exhibited in Paris, at the Hôpital Cochin, an account of which was read by M. Bally at the Académie Royale de Médecine. A man, twenty-five years of age, who had been ill for fifteen days, was admitted into the hospital with symptoms of typhous fever; he also complained of pain in the left thigh; and, whilst he was in a state of delirium, said he had been bitten on the knee by a dog. The limb was most attentively examined, but not the slightest trace of such an accident could be discovered. The thigh and scrotum were much swollen. He died the following day. On dissection, *eight hours after death*, the surface of the body was found soiled by blood, which had transuded through the integuments; and some blood had also been discharged from the nose. The whole body was emphysematous, but the left inferior ex-

‡ Op. Cit. vol. ii.

tremity was so to a very high degree. It was double its natural size, of a brown colour, and covered with numerous phlyctenæ—some black, of great extent, and collected in clusters, from which escaped a reddish serous fluid mingled with a quantity of gas; others white, from which nothing but air escaped. When the limb was pressed with the hand, crepitation was distinctly heard; the abdomen was much distended with gas; and in the intestines were observed those alterations that are so common in cases of typhous fever. Bubbles of air filled the vessels of the pia mater, and the left vena saphena. The lymphatic ganglions of the mesentery were enlarged and contained gas, *which took fire from the flame of a taper*, and produced an explosion; the same phenomenon also followed the exit of the air which was contained in the legs, thighs, and scrotum. A puncture was made into the abdomen, and the gas which escaped also took fire and burned for some time, the flame being blue at its base, and white at its summit: the combustion extended to the puncture which had been made with a trochar; the edges of this aperture became black, and were consumed, and the aperture itself was enlarged to double its original size. The gas which was contained in the subcutaneous cellular tissue was equally inflammable.*

This case is peculiarly interesting in consequence of the light it throws on the etiology of spontaneous combustion. On referring to the article on this subject it will be found that, in all those cases of spontaneous combustion of which we have an authentic history, the flame was communicated by the contact of a body in a state of ignition, and it is reasonable to suppose that the combustion was likewise supported by an inflammable gas generated within the body, as in the present instance.

Some doubt may be entertained whether this inflammable gas should be considered as the product of a putrescent decomposition formed by the ordinary laws of chemical attraction; or as a morbid secretion, the product of a vital action, and regulated by the same vital laws as other secretions.

On this subject much yet remains to be discovered, as our present knowledge only amounts to this, that collections of air are sometimes found in the living body, under circumstances where there is no appearance of their having been generated by fermentation or putrefaction; and that both in man and other animals, certain tissues possess the power of secreting gas, as, for instance, the swimming bladder in fish, the mucous membrane of the stomach and intestines in man, and the mucous membrane of the air-passages, which, as the accurate experiments of Dr. Edwards clearly prove, secretes a variable quantity of carbonic acid and azotic gases. The fact of a gaseous secretion being formed by certain tissues in the healthy state being established, we are authorized by analogy to conclude

that a secretion of gas may, like other secretions, take place as a morbid phenomenon in parts where no such secretion naturally occurs, more especially as we possess several well authenticated cases in which it is impossible to account for the presence of the gas in any other way. It must, however, be confessed that we are completely ignorant of the causes that influence the production of gaseous secretions, and of the condition of the solids or fluids most favourable to their development: if they are preceded or accompanied by any alterations of texture, they are such as entirely to escape our notice. The chemical composition of these secretions is also a desideratum.

Such being the state of our knowledge, we shall not enter into the consideration of any of the hypotheses which have been formed on this subject, but merely notice the fact, generally admitted by pathologists, that spontaneous emphysema is occasionally produced by a secretion of gas within the areolæ of the cellular tissue.

Dr. Baillie has recorded a very remarkable case of this kind, in which the emphysema was so extensive as to affect the alimentary canal and the mesentery, as well as the whole of the subcutaneous tissue; yet in which there was no solution of continuity through which the air could have been introduced, and no appearance of any putrefactive decomposition, by which it could have been generated. Frank likewise relates several cases of spontaneous emphysema, which it is difficult to account for on any other supposition than that of their being a product of morbid secretion; such, for instance, is the case of a young lady at Vienna, who became generally emphysematous during every paroxysm of a tertian fever, the emphysema disappearing as the paroxysm subsided. Many other curious instances of this disease are to be found in the chapter on PNEUMATOSIS, in the 8th volume of this author's work "*De Curandis Hominum Morbis*."

The *diagnosis* of emphysema seldom presents any difficulty when the disease affects the subcutaneous tissue, as it then produces an uniform swelling, sufficiently characterized by its lightness and elasticity, and by the peculiar crepitating sound and feel it yields under the finger, from the displacement of the air from one cell into another.

The *prognosis* must be regulated more by the cause of the emphysema, and the state of the respiratory organs, than by the extent of the emphysematous swelling. The emphysematous distention of the integuments is much more formidable in appearance than in reality, and, when unconnected with any lesion of the organs of respiration, may be very extensively diffused without producing any injurious consequences. Aristotle says that it was a common practice in his time to inflate the subcutaneous tissue of animals in order to make them fatten more readily afterwards: this practice is also alluded to by Pliny; and Schulze states that the only effect it produces on horned cattle is to render them dull and

* London Medical and Physical Journal, for June, 1831.

heavy for two or three days, after which time the emphysema gradually disappears, they recover their spirits and appetite, and in the course of six weeks become quite fat.* Haller and Soëmmering likewise attest the truth of these observations, which at least serve to prove that the effusion of air into the cellular tissue is not in itself productive of much injury, and that the sense of suffocation, and other formidable symptoms which so often accompany the progress of this affection, depend more on the diseases with which the emphysema is complicated than on the emphysema itself. This conclusion is further confirmed by the result of those cases of emphysema that have been observed in the human subject, uncomplicated with any lesion of the organs of respiration. Sauvages mentions the case of a soldier, who was found asleep in a cave by some persons who inflated his body through a quill until it scarcely retained a vestige of the human form,—all the lines of demarcation between the face, throat, and trunk being completely destroyed. In this case, which may be regarded as a rare example of general and extensive emphysema unconnected with any lesion of the respiratory organs, the principal symptoms observed were pain and stiffness from the over-distention of the integuments, and difficulty of breathing from the impeded motion of the thorax, and the congestion of the lungs, arising from the pressure which the superficial bloodvessels sustained; these symptoms disappeared as the air was evacuated through several scarifications which the patient had given himself with a knife, and his recovery was rapid and complete.

We may, therefore, conclude that the extreme difficulty of breathing, which so frequently accompanies traumatic emphysema, and which is in almost every instance the immediate cause of death in those cases that prove fatal, is in reality produced, not by the emphysematous distention of the integuments, but by the air effused into the sac of the pleura, or into the interlobular tissue of the lung.

Treatment.—The practice in emphysema must be regulated in a great measure by the cause of the affection, the extent of the emphysematous swellings, and the state of the respiration: the general indications of cure may, however, be arranged under three heads: 1. to arrest the progress of the emphysema, by preventing a further effusion of air into the cellular tissue; 2. to remove the air already effused; and, 3. to relieve the disordered state of the respiration. The means employed for the fulfilment of the first indication must be regulated by the cause of the emphysema.

In *spontaneous emphysema*, the only effectual method of arresting the further progress of the disease is, to correct the morbid state of the system on which the development of the gas depends, and of which it is merely

a symptom. As it generally occurs during the progress of asthenic or typhoid diseases, aromatic and stimulating liniments should be applied externally, in order to promote the action of the capillaries, while the proper remedies adapted to the disease are administered internally. Should the emphysema spread extensively, it may be proper to relieve the distention of the swollen parts by puncturing them with the point of a lancet.

In *traumatic emphysema*, arising from wounds of the larynx or trachea, the further effusion of air into the cellular tissue may be prevented by enlarging the external orifice of the wound, so as to make a direct passage for the exit of the air during expiration; the same practice should also be adopted when the emphysema arises from penetrating wounds of the chest, after which the wound should be closed with adhesive plaster.

When the emphysema arises from a fractured rib, the further effusion of air into the cellular tissue may be prevented by applying a tight roller round the chest, or by making small punctures through the integuments over the seat of the fracture.

When the breathing is not much oppressed, the application of a bandage may be employed with safety and advantage. But as (supposing that the surface of the lung is not adherent) the air is effused from the wounded lung into the sac of the pleura, before it escapes into the cellular tissue, it is plain that by applying a bandage round the chest in order to prevent the further progress of the emphysema, we only confine the air within the pleura, where, if it continues to accumulate, its presence must give rise to all the distressing symptoms of pneumothorax, as it not only compresses the wounded lung, but, by its pressure on the mediastinum and diaphragm, obstructs the dilatation of the other lung also: under such circumstances every facility for the enlargement of the chest becomes necessary, in order to admit as much air as possible into the lung, which still executes its functions; but the effect of the bandage is to diminish the dilatation of the sound side as well as that of the diseased, and, consequently, to increase still farther the embarrassment of the respiration.

For these reasons, it is much safer where the breathing is at all embarrassed, to let the air escape by making several punctures or small incisions over the broken rib, than to confine it with a bandage, though the latter practice may be employed with advantage in those cases where the quantity of air effused into the chest is not sufficient to produce much dyspnoea or oppression.

Lastly, in the cases of emphysema arising from over-distention and rupture of the air-cells, and the escape of air into the interlobular tissue of the lungs, and thence through the mediastinum into the common cellular tissue, the only method of arresting the further effusion of air is by employing such means as are calculated to diminish the violence of the respiratory efforts by which the air is forced,

* Dictionnaire des Sciences Médicales. Art. *Emphyseme*.

at each respiration, into the mediastinum. With this view copious venesection should be employed, for the double purpose of relieving the pulmonary congestion, and of diminishing the mass of the circulating fluid; for, by lessening the quantity of blood to be aerated, we also lessen the necessity for taking in so large a supply of air for its aeration, and in the same proportion diminish the efforts made by the muscles of respiration to dilate and contract the thorax. Opiates should likewise be employed with the same intent, to diminish, as Laennec expresses it, "le besoin de respirer;" rest and silence should be enjoined, and the antiphlogistic regimen strictly enforced.

We next come to consider the means of removing the air already effused into the cellular tissue. In the slighter cases of emphysema, where the breathing is not much oppressed, and the quantity of air effused is not very great, the power of the absorbents will generally be found sufficient for its removal, and it will only be necessary to employ friction over the tumid parts with camphorated liniment, or some other stimulating embrocation, for the purpose of accelerating the process of absorption: but when the quantity of air effused into the cellular tissue is so great as to produce considerable distention of the integuments, it will be advisable to make several punctures, with the point of a lancet, through the skin where it is most distended, in order to evacuate the air contained underneath. These punctures or scarifications should be made sufficiently deep to divide the cellular tissue, in order to make a free exit for the air from the deep-seated as well as from the superficial cells. If the air should have spread extensively over the body, it will be more advisable to puncture the skin wherever the parts are much inflated, than to press it along under the skin to the punctures which may have been made in a distant part. This practice should be adopted in all cases of extensive emphysema, from whatever cause it may have arisen; as it is perfectly free from danger, and affords immediate relief to the suffering arising from over-distention of the swollen parts, and likewise obviates the danger of the air forcing its way into the cellular tissue of the internal organs.

We have already seen that in the great majority of the cases of traumatic emphysema the organs of respiration are more or less injured, and that it is from the injury which they sustain that the most distressing and dangerous symptoms invariably arise. To them, therefore, our principal attention should always be directed as the most important object of our treatment. In all cases of extensive emphysema the breathing is more or less oppressed, in consequence of the diminished mobility of the thorax, and the congested state of the lungs caused by the increased quantity of blood thrown on them from the surface of the body. In such cases, therefore, it will be proper to relieve the internal congestions by copious bloodletting, and to remove the pressure which impedes the motion

of the thorax, by evacuating the air confined under the integuments as already directed. Venesection is also useful in such cases, as the most powerful means we possess of anticipating or arresting the development of inflammation.

Should these measures prove insufficient for the relief of the breathing, we may then infer, (especially when the sense of oppression and suffocation continue progressively increasing, and other symptoms indicate the existence of pneumothorax,) that air is accumulating within the chest, so as to oppress not the wounded lung only, which was collapsed and useless from the first, but the diaphragm and mediastinum, and through them the opposite lung also. A freer incision should then be made through the integuments over the seat of the injury, and if this does not afford sufficient vent to the air confined within, the incision should be continued through the intercostal muscles, and a small puncture cautiously made into the pleura. Mr. Hewson, who has written an excellent paper on this subject, in the third volume of the *Medical Observations and Inquiries*, recommends that the operation should be performed, as in cases of emphysema, on the fore part of the chest, between the fifth and sixth ribs at the right side, as there the integuments are thin, and in the case of air no depending drain is required; but if the disease is on the left side, he considers it more advisable to make the opening between the seventh and eighth, or eighth and ninth ribs, in order that we may be sure of avoiding the pericardium. The perforation of the pleura will be immediately followed by the escape of the condensed air, the pressure of which being removed, the mediastinum and diaphragm will regain their natural position, and the opposite lung will thus be enabled to resume the free and unobstructed discharge of its functions; after which the wound should immediately be closed with adhesive plaster, in order to prevent the alternate ingress and egress of air during the dilatations and contractions of the thorax. Should the symptoms of oppression and suffocation again return, the wound may be opened as occasion requires, and the accumulated air suffered to escape.

It sometimes happens that the necessity of performing the operation of paracentesis is apparent from the oppressed state of the breathing and other urgent symptoms of pneumothorax, but that from the nature of the accident, and the extreme distention of the integuments, it is difficult to ascertain at which side the operation should be performed;—a point in reference to which an error may be attended with the most fatal consequences, as actually occurred in a case recorded by Dr. Halliday. "The operation of paracentesis was resolved on in consultation, and an incision was accordingly made between the sixth and seventh ribs on the *left side* of the thorax. As soon as the opening was made into the cavity of the chest, every distressing symptom became more severe, and the patient scarcely

survived a quarter of an hour." On dissection, it was discovered that the operation had been performed on the sound side.*

In order to avoid the possibility of committing so fatal a mistake, the existence of pneumothorax, and its precise seat, should always be clearly ascertained by the physical signs of this disease furnished by auscultation and percussion (see PNEUMOTHORAX) before the operation is undertaken; and should the emphysematous state of the integuments prevent their employment, or obscure the indications which they afford, several punctures should be made over the chest, and the air pressed towards them, until the emphysematous swellings are reduced; after which, the precise extent and seat of the pneumothorax may be ascertained with that degree of accuracy which the labours of Laennec have rendered so characteristic of this department of medical science.

Some writers use the term emphysema in a more extended signification than that which has been assigned to it in this article, and apply it to all preternatural accumulations of air, in whatever part of the body they are situated. But, as these collections of air have each received distinct names, according to the cavities or organs in which they are situated, such as pneumothorax, tympanitis, physometra, &c. their description will find a more appropriate place in the articles respectively allotted to these subjects. Emphysema of the lungs alone forms an exception, and will therefore be treated of in the next article.

(R. Townsend.)

EMPHYSEMA OF THE LUNGS.—The morbid appearances presented by this disease have been noticed by Bonetus, Morgagni, Van Swieten, Storck, and other anatomists. In this country we have a very correct account of an emphysematous lung from the pen of Sir John Floyer; and Dr. Baillie's work on Morbid Anatomy contains an accurate description of the three principal circumstances which characterize this lesion, namely, the great size of the lungs, the dilatation of the cells, and the vesicles formed by extravasation of air under the pleura. The discovery of its frequent occurrence as a disease, of its etiology, and diagnosis, was, however, reserved for the pathological researches of M. Laennec. In order to render the following observations intelligible, it will be necessary to premise a few observations on the anatomical structure of the pulmonary parenchyma, as the emphysematous condition of this viscus is, in many cases, merely an exaggeration of its natural or healthy structure.

If we examine in a good light the surface of a sound lung, we can ascertain by the naked eye, through the transparent pleura, that its parenchyma is formed by the aggregation of a multitude of small vesicles of an irregularly spheroid or ovoid figure, full of air, and separated from each other by opaque white

partitions. These vesicles, which on the surface of the lungs have the appearance of small transparent points, are not of an uniform size; the largest are equal to the third or fourth part of a millet-seed. They are grouped in masses or lobules, divided from each other by partitions of closely condensed cellular membrane, very thin, yet thicker and more opaque than the partitions between the individual cells. These partitions traverse the pulmonary substance in all directions, and crossing each other under various angles, form figures of different shapes, such as lozenges, squares, trapeziums, or irregular triangles, the bounding lines of which are rendered still more defined by the black pulmonary matter that is deposited along them.*

If we analyze this structure, we find that it is composed, 1st, of the minutest ramifications of the bronchi, which go on subdividing and diminishing in caliber until they terminate each in a cul-de-sac or air-cell, as it is commonly termed, of extreme delicacy and minuteness, on the parietes of which the pulmonary vessels ramify in an extreme state of fineness;† and, 2dly, of the common cellular membrane which serves to connect these air-cells together, and which likewise forms several membranous partitions that divide each lobe into a number of distinct lobules, and is hence termed the *interlobular cellular tissue*, each lobule being as perfectly isolated from those adjoining it by this partition, as each lobe is by its investiture of pleura.

Each of these textures is liable to emphysema, and hence we have two varieties of this disease in the lung: 1. *the vesicular or true pulmonary emphysema*, (as it is somewhat arbitrarily termed by Laennec,) formed by the dilatation of the minute bronchi and air-cells, or by the rupture of their parietes, by which several contiguous cells are thrown into one; 2. *the interlobular emphysema*, formed by the infiltration of air into the interlobular cellular tissue. The former usually occurs as a chronic disease, while the latter as generally assumes the character of an acute affection.

I. *Pulmonary or vesicular emphysema.*—In pulmonary emphysema the size of the air-cells is much increased and is less uniform. The greater number equal or exceed the size of a millet-seed, while some attain the magnitude of hemp-seed, cherry-stones, or even French beans.‡ We are disposed to think, however, that cavities of such a size are rarely formed by the dilatation of individual cells, as in more than one hundred dissections which we have made of pulmonary emphysema, we never except in one instance saw the air-cells dilated to the size of a garden-pea; in the great majority of cases the cavities of this size, or even of a less diameter, are formed by several cells being thrown into one, in consequence of their delicate partitions being overstrained and ruptured. In some cases, the walls of the cells

* Forbes's Translation of Laennec.

† Reisseisen, De Structura Pulmonum.

‡ Laennec.

disappear from one entire lobule, leaving only some lacerated filaments traversing its cavity from one interlobular partition to another, and in some instances these partitions are also lacerated, and their respective lobules are thus thrown into one large cavity, which usually reaches the surface of the lung, and forms a projection under the pleura. In order to see these alterations of structure, it is necessary to inflate the lung and dry it previous to examination, as without this precaution the cells collapse immediately when cut into, and all appearance of emphysema is consequently lost.

"Emphysema may affect both lungs at the same time, one only, or a part of one, or both: in the latter case, and, indeed, in any case, as long as the disease is confined to a simple dilatation of the cells, or to the rupture of a few of their partitions, and does not form vesicles of any considerable size on the surface of the lung, it may be easily overlooked in the dead body; for this reason, the disease, which is really one of the most constant morbid appearances in all cases of protracted dyspnoea, has been as constantly overlooked, and in this way the lungs of asthmatic patients have been regarded as healthy when they are in reality emphysematous, and cases of dyspnoea set down as nervous or idiopathic, for which anatomy has now discovered an organic cause.

"When the disease exists in a very high degree, we cannot help being struck with the appearance of the parts. The lungs seem as if confined within their natural cavity, and when exposed, instead of collapsing as usual, they rise in some degree, and project beyond the borders of the thorax. If we examine them in this state, they feel firmer than natural, and it is more than usually difficult to flatten them. The crepitation they yield on pressure, or being cut into, is less, and of a kind somewhat different; it is more like the sound produced by the slow escape of air from a pair of bellows, and the air makes its escape from the cells much slower than in a healthy state of the organ. When we detach the lung, the crepitation is found to be still less perceptible, and the sensation conveyed by pressing the parts is very like that produced by handling a pillow of down. On placing an emphysematous lung in a vessel of water, it sinks much less than a healthy lung, and sometimes it floats on the surface with scarcely any obvious immersion. The pulmonary tissue is drier in a lung affected with emphysema than in a healthy one, and it is unusual to find even towards the roots of the lungs any trace of the common serous or sanguineous infiltrations usually found after death."* In some cases, however, especially when the heart is diseased and the pulmonary circulation much obstructed, the emphysematous lung becomes red and congested.

It seldom happens that emphysema exists to the extent so admirably described in the preceding paragraph, without occasioning the rupture of several of the dilated cells, and it is by no means uncommon to find one or more

large vesicular cavities formed, each by the reunion of all the air-cells of one entire lobule, and bounded by its interlobular partitions, which often remain uninjured when the texture of the air-cells which they enclose is completely destroyed; in extreme cases these interlobular partitions give way likewise, and several lobules are then thrown into one large vesicular cavity, resembling more a bladder filled with air or the vesicular lung of a frog, than the parenchymatous texture of the human lung. These alterations are most frequently observed at the margin of the lung or at its base where it reposes on the diaphragm.

From these observations it results that emphysema of the lung essentially consists in the rarefaction of its parenchyma, produced either by the dilatation of its cells, or the rupture of their parietes. These lesions may be referred to three principal causes: 1. hypertrophy; 2. atrophy; 3. over-distension of the air-cells.

1. *Hypertrophy.*—Laennec has remarked that in several cases where the lung has been rendered incapable of performing its functions, the other, having double duty to perform, acquires an increase of volume proportionate to its increased activity of function. This increase of size appears to result from an increase in the capacity of the capillary bronchi and air-cells, at the same time that their parietes are increased in thickness; indeed, this is rendered very evident by inflating and drying the lung, for when after this process it is cut into slices, we at once perceive some cells much larger than in the natural state, and likewise their parietes much thicker than they usually are. The state of the air-cells in this form of emphysema may be considered as analogous to the hypertrophy with dilatation of the heart and other hollow muscles.

2. *Atrophy of the lung.*—Whenever any cause continues for a certain length of time to impede the free entrance of air into the pulmonary cells, those cells diminish in number, and the parenchyma of the lung falls into a state of atrophy. Accordingly, we find this atrophy invariably taking place in lungs which have been compressed by pleuritic effusions of long standing, or when the principal bronchial tube is compressed by external tumours. In old age, likewise, the lungs sometimes undergo so considerable a degree of atrophy that the chest is visibly contracted in consequence; and in such persons they are small, contain very little blood, are remarkably light, and their whole texture appears rarefied. If we inflate and dry a lung in this state, we perceive a remarkable alteration in the disposition of the ultimate bronchial ramifications, and of the air-cells in which they terminate; they no longer form distinct cavities, separated from each other by complete septa: at first these septa are only reduced to a state of extreme tenuity, but at a later period some of them appear perforated in one or more points, while others seem ruptured and irregularly torn. In some cases the walls of the cells disappear altogether, and we only find in their stead

* Forbes's Translation of Laennec.

some delicate filaments traversing in different directions cavities of various sizes. In the parts of the lung where these alterations exist, there are no longer to be found either bronchial ramifications, or air-cells, properly so called, but merely vesicles of greater or less diameter, divided into compartments by imperfect septa or irregular laminæ, bearing a perfect resemblance to the lungs of cold-blooded animals.*

Thus we see how lesions the most opposite in their characters, hypertrophy and atrophy, may alike produce this disease. But in the case of hypertrophy there is only dilatation of the cells without laceration of their parietes, unless as an accidental occurrence; whereas, in atrophy of the lung, large cavities are formed by several cells being thrown into one by the extenuation and rupture of their walls. Hence arises this important difference, that in the first case the number of surfaces on which the blood is exposed to the action of the air remains the same, while in the second the number of these surfaces is considerably diminished. It is easy to see that the respiration will not be equally affected in these two cases, and that the dyspnoea must necessarily be more considerable in the latter. There is, however, one circumstance that occurs in old age (at which period this alteration, as already stated, most generally occurs,) which prevents the respiration from being as much embarrassed as we might *à priori* have expected,—namely, the diminution that takes place in the quantity of the blood, or (what comes to the same thing) the diminution in the rapidity of the circulation. For this reason atrophy of the lung, when occurring in old age, should rather be regarded as a natural phenomenon resulting from the fulfilment of a law in the animal economy which establishes a constant proportion between the quantity of blood to be aerated in a given time, and the extent of surface on which this aeration is to be accomplished. Thus we find that the lung has its maximum of density in infants, and in those animals that have either a very rapid circulation or a very large supply of blood, and that, on the contrary, the density of the lung is at its minimum in old persons, and in such animals as receive into their lungs, at each round of the circulation, only a small proportion of the blood contained in their circulating system.†

Besides these, which may be considered as the physiological causes of pulmonary emphysema, there are others which produce a similar condition of the organ in a manner purely mechanical, by keeping the air-cells in a state of over-distention. Amongst these may be enumerated violent efforts of any kind (especially if often renewed) which cause the long-continued retention of the breath; repeated attacks of catarrh, bronchitis, asthma, or other diseases of the lungs or air-tubes, attended with difficulty of breathing, or distressing paroxysms of coughing.

The mechanism of the over-distention and rupture of the air-cells in these cases may be explained by the efforts which are constantly made by the powerful muscles of inspiration to introduce a fresh supply of air into the air-cells, while that which they contain is prevented from escaping by pellets of viscid mucus, spasmodic stricture of the bronchi, or turgescence of the bronchial membrane, according to the nature of the disease which produced the dyspnoea. In this way, the air-cells are kept in a state of over-distention which the efforts that are made to evacuate them only tend to confirm and increase; and provided the obstruction is of some continuance, the dilated condition of the cells will be rendered permanent, or else their parietes will give way, and allow several cells to be thrown into one.

From this view of the matter, it will readily be understood why all diseases accompanied by protracted attacks of dyspnoea, or violent and often repeated paroxysms of coughing, are so constantly followed by emphysema, especially when occurring in persons advanced in life, in whom, as we have already explained, the lungs are peculiarly predisposed to this disease by the atrophy which their parenchymatous texture naturally undergoes at this period of life. But though the over-distention and rupture of the air-cells is in general a slow process produced by long repeated efforts to overcome an obstruction to the free exit of their contents, and is consequently the result, in most cases, of some chronic affections of the bronchial tubes, such as dry catarrh, asthma, or the congested state of the mucous membrane, so frequently produced by organic lesions of the heart; it may likewise be produced in a very short space of time, when the efforts made by the muscles of respiration are violent and constantly repeated. We have frequently found the lungs emphysematous in children dying of whooping-cough; and in one instance, where the whooping-cough had not lasted longer than three weeks, we saw several cells dilated to the size of garden-peas, of a globular form, and with their parietes evidently hypertrophied.

From whatever cause the emphysema proceeds, its constant effect is to render the portion of lung affected incapable of performing its respiratory functions, as is evident from the absence of respiratory murmur in the part during life, and the difficulty with which the air escapes from the overstrained or ruptured cells, even after the lung has been removed from the body. Moreover, as the emphysema is in almost every instance originally produced by turgescence of the bronchial membrane, or spasm of the circular fibres, so from an effect it generally becomes a cause, and maintains the disease by which it was originally excited. Accordingly we find that persons labouring under emphysema of the lung are particularly liable to attacks of asthma and bronchitis, and, as a consequence of the latter, and of the efforts made during respiration, to hypertrophy or dilatation of the heart. These intercurrent diseases usually occur only after long intervals during the first

* Andral's Pathological Anatomy.

† Andral, Op. Cit.

years of the disease; but when the complaint is of long standing, and the patient is far advanced in life, the paroxysms become more frequent and more severe, each succeeding attack increases the extent of the organic lesion and rupture of the pulmonary tissues, and sometimes interlobular emphysema then ensues.

From these observations it may be concluded that pulmonary emphysema in a moderate degree is not a disease of great severity, and that the principal danger is to be apprehended from the repeated attacks of bronchial disease by which the emphysematous condition of the lung was originally produced, and to which, in its turn, it seems to act as a predisposing cause.

From the pathology of emphysema, its diagnosis and treatment may be easily deduced. The dyspnœa, which is its most constant symptom, depends in a great measure on the extent of the disease, and the age and constitution of the individual. When the emphysema is rapidly formed, occupies an extensive portion of the lung, and occurs in a young plethoric subject, through whose lungs a large quantity of blood is constantly in circulation, the dyspnœa which ensues may be so great as to terminate rapidly in asphyxia. But when, as is much more frequently the case, the emphysema commences slowly and proceeds gradually, the disease is in itself seldom attended with any immediate danger, although it renders the organ obnoxious to serious or even fatal effects from contingent pulmonary disease, which in a healthy lung might be borne with comparative impunity.

The difficulty of breathing which accompanies this disease is constant, but is aggravated by paroxysms, which are irregular both in the period of their return and their duration; it is likewise increased by all causes which usually increase dyspnœa from whatever source arising, such as the action of digestion, flatulence in the stomach or bowels, anxiety, living in elevated situations, strong exercise, running, or ascending a height, and above all by the supervention of an acute catarrh, to which, as already stated, persons affected with emphysema are peculiarly liable. Between the paroxysms there is no fever, and the pulse is generally regular. In slight cases the complexion and habit of body are little altered; but when the affection is more considerable, the skin usually assumes a dull earthy hue, with a slight shade of blue interspersed, and the lips become violet, thick, and swollen; there is likewise more or less of cough usually present, though it is sometimes so slight as to escape the notice of the patient: the expectoration generally consists of a greyish viscid mucus. These symptoms may, however, be considered as appertaining more properly to the disease of the bronchi with which the emphysema is complicated, than to the emphysema itself.

When the emphysema is confined to one lung, or is much greater in one than in the other, the side most affected is perceptibly

larger than the other, its intercostal spaces are wider, and it yields a clearer sound on percussion. If both sides are affected equally, the whole chest yields a very distinct sound, and, instead of its natural compressed shape, exhibits an almost round or globular outline, swelling out both before and behind: this conformation of the chest is sometimes so remarkable as to render the existence of the disease evident from simple inspection.*

The pathognomonic signs of this disease are furnished by a comparison of the indications furnished by percussion and auscultation; for while the sound elicited by percussing the chest over the part affected is perfectly clear, or even tympanitic, the respiratory murmur is extremely indistinct, or even completely extinct, and in its place a slight sibilous râle only is heard even during the forced inspirations that precede the act of coughing. These indications will be confirmed by the long continuance of the disorder, and the existence of an habitual dyspnœa, occasionally aggravated by asthmatic paroxysms.

When the disease is so far advanced as to form large vesicular cavities under the pleura, its presence may be recognised by a sound heard during inspiration or coughing, which is quite pathognomonic, and described by Laennec under the appropriate name of the *crepitous râle with large bubbles*. The sound of this râle he compares to that which would be produced by blowing into half-dried cellular membrane. We have repeatedly verified the accuracy of this comparison, and have uniformly found on dissection that the sound in question was produced either by an extreme state of vesicular emphysema, or by the interlobular form of the disease; we have often found these alterations on dissection in cases where this premonitory sound was never discovered.

There is another stethoscopic sound which Laennec describes as belonging exclusively to interlobular emphysema, but which we have heard on more than one occasion, in cases of vesicular emphysema where the ruptured air-cells projected above the surface of the lung. We allude to the "*friction of ascent and descent*," as Laennec terms it, which is a sensation or sound of one or more bodies rubbing against the ribs, and rising and falling during the alternate movements of inspiration and expiration. The friction of ascent takes place during inspiration, the friction of descent accompanies expiration, and is much more constantly audible than the other sound. Most commonly the friction seems to take place against the costal pleura; at other times it appears to have its site against the diaphragm or mediastinum, or between the lobes of the lungs. These sounds are sometimes accompanied by a crepitation perceptible to the hand.

Treatment.—As pulmonary emphysema must, in almost every instance, be regarded as

* Laennec, Op. Cit.

an *accident* caused by some prior disease of the lung, the first indication should obviously be to remove the original disease, as the most effectual means of removing its effect, or, at least, of preventing its farther extension. This is perhaps as much as we can reasonably hope to accomplish in this case, as it is difficult to conceive how any method of treatment should restore that portion of lung which has once become emphysematous to its original healthy condition. M. Laennec, however, is of opinion that this affection should not be considered as altogether incurable; and that, if we can diminish the intensity of the cause which keeps up the habitual distention of the cells, we may in the end hope that these will be actually lessened in volume. With this view the cause of the emphysema should be combated by prompt and active treatment, and the patient should be made to abstain from all the ordinary exciting causes of dyspnoea, as they not only produce present distress, but likewise keep up the over-distention of the cells, and consequently increase the extent of the emphysema.

It has already been stated that emphysema in a moderate degree is not a disease of great severity, and that it is from the supervention of attacks of asthma or bronchitis that the principal distress and danger are to be apprehended. Every precaution should therefore be adopted to remove these affections and prevent their recurrence.

To detail the treatment of these diseases here would be to repeat what has been stated in other parts of this work: we therefore refer the reader to the articles *ASTHMA*, *BRONCHITIS*, and *CATARRH*, for all the information that can be obtained on the subject in the present state of our experience.

Laennec recommends frictions with oil as useful in diminishing the susceptibility to be affected with catarrh; but a more effectual method of accomplishing this object is by sponging the chest every morning with vinegar and water, and afterwards dry-rubbing the part with flannel or a flesh-brush, as recommended in *ASTHMA*. In the case of pallid cachectic patients, the subcarbonate of iron has occasionally seemed to have a similar effect, and to tend at the same time to diminish the congestion of the mucous membrane, and also the spasmodic stricture of the bronchi. It is also of importance to attend to the state of the digestive organs, as experience has fully proved that irritation of the bronchial membrane is very often a sympathetic affection depending upon irritation of the stomach. Whatever, therefore, is improper for a dyspeptic patient should be avoided by those who labour under emphysema of the lungs. Warm clothing in all cases of delicate mucous membranes is particularly necessary, and flannel should be worn next the skin during the day, the lower extremities should be kept especially warm, and other necessary precautions adopted to guard against the cold of the winter months.

We have known many persons affected with emphysema of the lungs, and that to a very

considerable extent, whose breathing was quite good during the summer months, but who dreaded the approach of winter as the never-failing harbinger of their sufferings. For such cases the only alternative is to spend the winter in a more congenial climate. Indeed there is, perhaps, no class of complaints in which the beneficial effects of change of air and climate are more decidedly manifested than in those chronic cases of pulmonary emphysema complicated with great susceptibility of irritation in the mucous membranes of the air-passages.—(See *CLIMATE*.)

II. Interlobular emphysema.—This, as its name implies, consists in an effusion of air into the cellular tissue, which intersects the pulmonary parenchyma, and divides each lobe into a number of distinct lobules. This form of pulmonary emphysema may be easily recognised in the dead body, by the transparency of the interlobular partitions, which contrast strongly with the denser structure of the intervening portions of parenchyma. Instead of the scarcely perceptible thinness which they exhibit in the natural state, these partitions, in a state of emphysema, are distended to the breadth of two or three lines, or even of an inch in some cases. They are generally widest at the surface of the lung, where the distention of their delicate cells bears an apt resemblance to a string of glass beads. Sometimes the emphysema is confined to two or three interlobular partitions, which run parallel to each other from the margin of the lung; in some cases these parallel bands are intersected by transverse partitions likewise in a state of emphysema, and the lobules intercepted between these intersecting partitions are thus completely insulated, being surrounded on all sides by transparent cellular tissue in a state of emphysema.

When the disease continues to extend, the air passes from one interlobular partition to another until it reaches the root of the lung, from whence it soon extends to the mediastinum, and thence spreads all over the cellular tissue of the trunk.—(See the preceding article.)

It sometimes happens in this form of the disease that the air escapes into the cellular tissue which connects the pleura to the lung; in this way one or more bubbles of air are formed immediately under the pleura, and may be pushed along the surface of the lung by the finger,—by which circumstance they may be distinguished from the vesicles that are formed in the true pulmonary emphysema, as the latter are prevented from being displaced in this way by their interlobular partitions.

The formation of interlobular emphysema is explained by M. Laennec as necessarily depending on a rupture of some of the air-cells, and the consequent extravasation of the air contained in them into the cellular substance surrounding the lobules. It must, however, be admitted that, even in the most extensive cases of this disease, no such rupture has ever been detected, and that the rupture of several cells constantly takes place, and yet not a

particle of air finds its way into the interlobular partitions; nay, that these partitions may themselves be lacerated, and yet no interlobular emphysema be produced. Farther observations are required to elucidate this subject.

This form of emphysema is as rare as the other is common. It is very seldom combined with the true pulmonary emphysema; and in the great majority of cases seems to result from some sudden and violent effort of the respiratory muscles, as in the forcing pains of child-birth, in raising heavy weights, in hooping-cough, &c. Notwithstanding the greater density of their lungs, children appear to be more liable to this disease than adults.*

The only symptom from which the existence of this disease can be suspected, is the sudden supervention of dyspnoea after any violent effort of the lungs. Its stethoscopic signs are the dry crepitous râle with large bubbles, and the friction of ascent and descent already described. These sounds, it will be recollected, are likewise common to the vesicular form of emphysema when the pleura is projected by several air-cells thrown into one; perhaps the only method of distinguishing between these cases is by the sudden supervention of the dyspnoea and of the stethoscopic signs in the interlobular form of the disease: fortunately, however, the diagnosis is not a matter of much practical importance, as in the slighter cases (in which alone any ambiguity can exist) the air appears to be always absorbed, and the interlobular partitions gradually return to their natural state. When the aerial infiltration extends to the external parts, the difficulty of diagnosis is at once removed, and the disease may be treated on the principles already stated in the preceding article on general emphysema.

(R. Townsend.)

EMPHYEMA. *Ἐμπίημα*, formed of *ἐν* and *πύον*, literally signifies an internal collection of pus, and in this general sense was employed by several ancient authors. By subsequent writers its signification has been considerably restricted, and nosologists now apply the term exclusively to those collections of pus which are contained within the sac of the pleura. In practice, however, it is not always easy to determine, *a priori*, the precise nature of the fluid collected within the chest, as its physical characters are found to vary considerably, even in those cases that most closely resemble each other in their origin, progress, and symptoms. In a case of empyema of two months' standing, occasioned by the bursting of a tuberculous abscess of the lung into the pleura, the effusion, as observed by the writer, presented all the characters of genuine pus; while in another case, where the pleuritic effusion was produced by a similar cause, and assumed the same chronic form, the operation of paracentesis gave issue to a fluid as transparent and colourless as water.

Other varieties, to be presently enumerated, have likewise been observed in the appearance and composition of these fluids; and as there are no peculiar symptoms by which we can always discriminate their precise nature during the lifetime of the individual, the term is now generally used without any reference to the puriform character of the effusion.

When effusion into the thorax takes place in an individual of a dropsical diathesis, and seems to result from an obstruction to the circulation and the consequent transudation of the serous part of the blood, rather than from any irritation of the secreting surface, the disease is denominated *hydrothorax*. When the effusion is known to consist of blood, as in penetrating wounds of the chest, where the pulmonary or intercostal vessels have been injured, the term *hæmothorax* is used to express it; and the name of *pneumothorax* is applied when the effusion is of a gaseous nature. With these exceptions, all cases of effusion into the pleura that are sufficient to compress the lung and impede the function of respiration, are comprehended under the generic appellation of *empyema*.

The pleura, like other serous membranes, constantly exhales a fluid, in the form of vapour, by which its surface is lubricated and moistened. In the natural state, this perspiratory fluid always exists in the form of halitus or vapour; but in a morbid state, it is sometimes exhaled in much larger quantities, and instead of vapour assumes the fluid form. Its qualities are then also materially altered, so that, instead of a slight moisture barely sufficient to facilitate the gliding motion of the opposing surfaces on each other, the serous sac is filled with certain morbid secretions, of which the following are the principal:—

1. Serum: its composition is sometimes the same as that of the blood, and sometimes differs from it in containing a greater or less proportion of albumen.
2. The same combined with a certain quantity of the colouring matter of the blood.
3. Pure blood.
4. Pus.
5. The spontaneously coagulable and organizable matter of which false membranes are formed, and which, in their turn, are liable to undergo various morbid alterations: thus they may become inflamed and form new false membranes, or exhale blood, or secrete pus, melanosis, or tubercle; or lastly they may be transformed into fibrous, cartilaginous, or osseous tissue.*

These morbid productions, either singly or variously combined, form the principal, if not the only ingredients in all cases of pleuritic effusion.

Our knowledge of the pathology of pleuritic diseases in general, and of empyema in particular, has been considerably advanced of late years by the labours of Laennec, Broussais, and Andral, whose works, (*Traité d'Auscultation Médiate, Histoire des Phlegmasies*

* Laennec.

* Andral, Anatomie Pathologique.

Chroniques, Clinique Médicale.) contain the most complete history we possess of these diseases, and may indeed be said to form a new era in the pathology of this class of affections.

The effusion of empyema, it is now generally admitted, is in all cases principally, if not entirely, formed by a morbid secretion from the pleura, and may in almost every instance be referred to inflammation of that membrane, either in an acute or chronic, an evident or latent form; and even in those cases where pus or other matter is introduced into the pleura from an extrinsic source, as from the rupture of a pulmonary or hepatic abscess, the collection of fluid which constitutes the empyema consequent thereon, does not consist so much of the matter of the abscess as of the morbid secretion from the pleura which the irritation caused by the presence of that matter produces.

The nature of the exudation in acute pleuritis, and the successive stages of its organization and conversion into false membrane, are detailed in a separate article in this work. (See PLEURITIS.) For our present purpose, it is only necessary to consider those morbid secretions of the pleura which evince no disposition to become organized or absorbed, but continue to accumulate in the shut sac of that membrane, where they act as a foreign body, and, by their pressure on the important organs contained within the parietes of the chest, present a constant obstacle to the due performance of their functions.

In some cases the effusion consists of a clear, transparent, or lemon-coloured serum; sometimes the effused fluid, though it still retains its transparency, contains several floculi of albumen, some suspended and others precipitated to the bottom. More frequently it is rendered quite turbid by the quantity of these minute floculi that are partially dissolved and suspended in it, while the pleura, more especially the most dependent portion of it, is covered with an inorganic layer of a white or yellowish paste formed by these floculi, which fall in the form of a sediment to the bottom of the fluid in which they were suspended. In other cases, and they are by far the most numerous, the effusion is still more turbid, and of a greyish brown or yellow colour—in short, it exhibits every intermediate variety of appearance until it presents all the characters of genuine pus.

These different varieties of effusion are sometimes mixed up with the contents of abscesses formed in the neighbouring parts, as in the lungs or liver, and discharged into the pleura. In some cases the effusion is coloured by the admixture of a certain quantity of blood, and in some rare instances the effusion has been found to consist entirely of blood. This sanguinolent effusion sometimes occurs at the very onset of the pleuritic attack, constituting the *primitive hemorrhagic pleurisy* of M. Laennec, but is more frequently observed to occur at a more advanced stage of pleurisy, particularly at the time when vessels begin to be formed in the false membranes,

or when a fresh attack of inflammation supervenes in them. Much importance was attached by the older writers to the decomposition of these effusions and their tendency to putrescency; but the best pathologists are now agreed that they never acquire an offensive odour, or exhibit any sign of decomposition unless when the parietes which enclose them become gangrenous, or when a communication has been established between the fluid and the external atmosphere.*

The quantity of these effusions is sometimes so very great as to compress the lung into the smallest possible compass, and exhaust it of its air more effectually than could be done after death by means of an air-pump; at the same time the parietes of the chest which are in any degree susceptible of motion are distended to the utmost; the ribs are elevated, and their lower margins everted, so as to increase their capacity as much as possible; the intercostal spaces are protruded; the diaphragm is forced down into the abdomen, and the abdominal viscera are consequently displaced, especially the liver, which, in cases of extensive empyema of the right side, has been known to descend into the iliac fossa.† The mediastinum, in like manner, yields to the distending force of the effused fluid, compresses the opposite lung, and allows the heart to be thrust completely out of its natural situation. We shall presently see that this displacement of the heart is one of the most constant and least fallible symptoms of empyema. Without this great enlargement of the affected side, it would be physically impossible that one sac of the pleura could accommodate such an enormous quantity of fluid as has occasionally been found there.

A patient of Dr. Croker, of Dublin, was lately operated on for empyema by Mr. Crampton, when the almost incredible quantity of fourteen imperial pints of pus was drawn off from the left pleura. In Dr. Archer's case of successful paracentesis of the thorax, recorded in the second volume of the Transactions of the Dublin Association, eleven pints of an inodorous fluid were drawn off, and in a few weeks after the patient was quite convalescent. Many other instances might be quoted of effusions equally great, or even still more extensive.

When the effusion is removed, it seldom happens that the pleura is exposed to view, as its surface is almost invariably covered with a coating of adventitious matter, which gives the interior of the chest much more the appearance of the walls of a large abscess than of a cavity lined with serous membrane. When, as in cases of latent pleurisy, the pleura is covered with a layer of the inorganic sediment, which is deposited when the effusion is wholly puriform, the layer of matter may be scraped off with the handle of the scalpel, and then the membrane underneath presents

* Andral and Broussais, Op. Cit.

† Stoll, Ratio Medendi.

an opaque blueish appearance, as if caused by the maceration to which it had been so long submitted. A few red dots or striae, as if laid on with a pencil, are generally dispersed over its surface; the membrane itself is seldom if ever really thickened, its apparent thickening being in almost every instance caused by a coating of adventitious membrane, which had been exuded during the earlier stages of the inflammation. When the chronic pleurisy succeeds to an acute attack, this apparent thickening of the pleura is a very constant appearance: sometimes the adventitious membrane forms a delicate transparent pellicle which appears perfectly incorporated with the subjacent membrane, but may however be dissected from it in one or more layers; sometimes the pleura is closely studded with minute transparent or opaque granulations of a flattened form, but most frequently the adventitious coating is of an opaque whitish colour, and varies in consistence from curd or soft cheese to fibro-cartilage, to which substances it often bears a very strong resemblance; and as it is generally composed of several strata laid one over the other, it sometimes forms a dense solid layer many lines or even inches in thickness. When a coating of this description is developed on the pulmonary pleura, it forms such an unyielding envelope round the lung in its compressed, contracted state, as must effectually prevent its expansion when the pressure of the fluid is removed; and as the lung in this condition cannot dilate itself promptly enough to keep pace with the progress of absorption, when the disease terminates favourably, the parietes of the chest must necessarily fall in to occupy the space left by the removal of the fluid: in this way is produced the *contraction of the chest* which so constantly follows the removal of a chronic effusion from the pleura either by absorption or evacuation.

The adventitious membranes which line the pleura are liable to a variety of morbid alterations; they are evidently susceptible of inflammation, and likewise of ulceration; for in many cases they have been observed eroded, as it were, with small circular pits, sometimes shallow and sometimes penetrating through the whole thickness of the false membrane: occasionally these penetrating pits communicate with each other by sinuses, or by a more extensive separation of the false membrane from the subjacent pleura, but at other times the ulceration penetrates through the pleura itself. When this happens on the costal pleura, it sometimes gives rise to the formation of external tumours, which either burst externally and discharge the matter of the empyema, or else form one or more sinuous passages by which the pus is infiltrated into the subcutaneous and intermuscular cellular tissue; but when it takes place in the pulmonary pleura, a communication is eventually formed with a bronchial tube, through which (according to the position of the body at the time) part of the fluid escapes, or air enters. Several cases illustrative of these morbid appearances

are recorded in Dr. Duncan's interesting essay on empyema and pneumothorax in the 28th volume of the Edinburgh Medical Journal. The pleura and its adventitious coating of false membranes is likewise subject to gangrene, and the detachment of the gangrenous eschars sometimes serve, as in the case of simple erosion just noticed, to form an outlet by which the matter of the empyema is evacuated.

These false membranes are likewise liable to other morbid changes. Sometimes they are transformed into fibrous or cartilaginous tissue, and in some instances they have been found completely ossified; they are also liable to the development of various morbid productions, particularly tubercle. The tubercles that are formed in false membranes are generally small and very numerous. We have, however, once or twice seen tubercles as large as filberts, in the adventitious coating of the pleura; their development is usually a slow process, and generally occurs in cases of very chronic pleuritis; but sometimes they are generated in great numbers with an extraordinary rapidity. M. Andral has seen the false membranes studded with tubercles in persons who died of acute pleuritis of only fifteen days standing.*

The morbid alterations which we have described may exist in both sacs of the pleura at the same time, constituting the double empyema of authors, or, as much more commonly happens, may occupy one side of the chest; or, lastly, may be limited to a part of one side. When the inflammation is limited to a certain extent of the pleura, the effusion is generally circumscribed by adhesions which prevent its creeping into the general sac of the pleura; these circumscribed empyemas, as they are termed, may exist between the lower lobe of the lung and the diaphragm, or between two contiguous lobes, between the inner surface of the lung and the mediastinum, or between any part of its outer surface and the costal pleura. Not unfrequently there exist between the pleura costalis and pulmonalis a number of dense firm adhesions, which, like so many shelves or partitions, intersect the effusion, and divide the sac of the pleura into a number of distinct compartments. We examined the body of a patient who died of empyema in the Whitworth Hospital, in March 1830, in whom the effusion was divided by these partitions into three compartments, so perfectly distinct from each other, that had the operation of paracentesis been performed during life that compartment only could have been evacuated into which the incision had been made; so that in order to draw off the entire effusion, it would have been necessary to perform three several operations.

The effect of the effusion in compressing the lung and diminishing its volume, has already been alluded to. When the effusion is very extensive, the lung becomes flattened and

* Clinique Médicale, vol. ii.

completely flaccid, and its surface corrugated like the shrivelled rind of a withered apple; in this state the pulmonary tissue is soft, pliant, and dense, like a piece of skin, without any crepitation, more pale than natural, and almost entirely without blood; its blood-vessels are flattened and frequently appear quite empty.* The lung thus circumstanced is incapable of expanding for the admission of air so long as the fluid continues to press on its surface: its alveolar texture, however, continues very distinct; and, when its surface is not coated with an unyielding false membrane, it may be readily restored to its full dimensions by inflation. The usual position which the lung thus compressed occupies, is by the side of the spinal column, against which it sometimes lies so close as to have escaped the observation of several distinguished anatomists, who accordingly described it as totally destroyed by suppuration. Its position may, however, be materially altered by adhesions attaching it to different points of the thoracic parietes, and preventing its receding from them. We have known the lung retained in close contact with the whole anterior part of the chest, while the fluid was accumulated in the posterior part. Andral records a case of empyema, in which the upper and middle lobe of the right lung were retained in their natural position by adhesions, and formed a complete roof over the effusion, which filled the whole of the lower part of the chest.† Drs. Graves and Stokes relate two remarkable cases of empyema in the fifth volume of the Dublin Hospital Reports, in both of which the lungs were attached from their apex to their basis by a vertical adhesion of about two inches in breadth. Other observations might be adduced illustrative of the effects of adhesions in preventing the lungs receding from the parietes of the thorax; but for our present purpose it is sufficient to remark that, as there is no part of the pulmonary pleura which may not contract adhesions with the corresponding surface of the costal pleura, so there is no part of the chest with which the lung may not be retained in contact, even in cases of very copious effusion. The knowledge of this anatomical fact is, as we shall presently see, of considerable importance in some cases for determining the presence of empyema, and likewise for selecting the site of the operation of paracentesis.

The lung, when compressed in the manner we have described in the preceding paragraph, is seldom attacked with inflammation; indeed its exanguineous condition would seem to guarantee it sufficiently from attacks of that nature; but there is another morbid alteration which the lung under such circumstances frequently presents, namely, the development of tubercles. M. Broussais supposes that their formation is in most cases consequent to the effusion, and in a great degree, if not altogether, produced by the obstruction of the

lymphatic circulation in the part.* A more general opinion however is, that tubercles are in this, as in other cases, the result of a general diathesis, and had probably existed in the lung before the effusion had taken place. M. Broussais's opinion, if correct, would furnish a strong argument in favour of operating at an early period of the effusion, in order to anticipate, if possible, the formation of the tubercles. Another morbid appearance which the lung occasionally presents is the formation of a gangrenous or phlegmonous abscess, by which, when the pleura is perforated, the effused fluid finds a passage into the bronchi, and is expectorated.

Such are the principal morbid appearances that have been observed after death in cases of empyema: it now remains for us to investigate the causes of these anatomical lesions, and to consider the symptoms to which they give rise, and by which they may be distinguished during life. We shall thus be prepared to form a correct estimate of the progress and termination of this disease, and of the remedies best calculated to arrest its progress and remove its effects.

We have already seen that the matter of empyema is in most cases formed exclusively by a morbid secretion from the pleura, and that, even in those instances where pus or other matter is introduced into the pleura from the rupture of an adjacent abscess, the empyema which follows is principally formed by exhalation from the inflamed pleura. It may, therefore, be assumed that inflammation of the pleura is the proximate cause of empyema. As, however, the ordinary course of pleuritic inflammation is not to terminate in empyema, but in the exudation of a compound fluid, the serous portion of which is subsequently absorbed, and the solid part organized and converted into false membrane, it becomes a question to determine what are the circumstances that cause the inflamed pleura to secrete the inorganic matter of empyema rather than the ordinary organizable product of pleurisy, or, in other words, what are the species of pleuritic inflammation which have the greatest tendency to terminate in empyema.

These may be divided into four classes:

1. Acute pleuritis of intense violence.
2. Acute pleuritis degenerating into the chronic form.
3. Inflammation of the pleura of so low a type as not to present the ordinary symptoms of acute pleurisy.
4. Pleuritis caused by the introduction of foreign substances.

1. *Acute pleuritis of intense violence.*—It very rarely happens that inflammation of the pleura is so intensely violent as to induce gangrene. When it does occur, a copious effusion always follows. More frequently, when the pain and other inflammatory symptoms present an unusual degree of violence, blood is effused from the inflamed surface; generally speaking, the effusion of fluid is more abun-

* Laennec, Op. Cit.

† Clinique Médicale, vol. ii.

* Op. Cit. vol. i. p. 343.

dant in the hemorrhagic than in the simple pleurisy, and the tendency to absorption is much less.* Lastly, when the pleuritis assumes this violent intractable character, a copious secretion of puriform matter may take place at an early stage of the disease. In a young woman who died in the Hardwicke Fever Hospital in the year 1826, after experiencing for twelve days before her death the symptoms of most violent inflammation of the pleura, we found, on dissection, nine pints of thick inodorous pus in the right pleural sac. M. Andral records another case in which a purulent effusion was formed with equal rapidity. Although the inflammatory symptoms were combated from the very outset of the disease by the most active treatment, on the fifth day the whole of the right side sounded dull on percussion, and respiration had ceased to be audible there; on the seventh, the side was evidently dilated; and on the eleventh, when the disease terminated fatally, the right side was found, on dissection, so filled with pus that the lung was completely condensed and flattened against the spine.† Piso likewise relates several cases of acute pleuritis, in which the patients died on the fifteenth, and some even so early as the ninth day, *with their sides full of pus.*‡ In those acute cases of empyema, the diagnosis is never difficult; the extreme violence of the symptoms, the acute pain of the side rendered almost insupportable by coughing, the excessive dyspnoea, general anxiety, and high fever, at once point out the highly inflamed state of the pleura, and awaken our attention to the possibility of its terminating by effusion: when under such circumstances the physical signs of effusion (to be presently described) rapidly supervene, the existence of empyema is placed beyond a doubt. This acute form of empyema is, however, much more rare than those chronic forms of the disease we are next to consider.

2. *Acute pleuritis degenerating into the chronic form.*—In the greater number of pleurisies which terminate favourably, the process of the absorption and organization of the effusion is completed within a limited period, which, at an average calculation, may be estimated at three weeks or thereabout.§ Whenever the symptoms of pleuritic inflammation outlast this period, or when, after a temporary abatement of the inflammatory symptoms, the patient is seized with rigors and irregular febrile paroxysms similar to those of remittent fever, there is reason to fear that the disease is about to assume the chronic form, and empyema may be apprehended. In many cases the passage of the disease from the acute into the chronic form may be traced to the circumstance of its having been neglected during its earlier stages, or not combated by sufficiently active treatment, or else to some indiscretion on the part of the patient during conva-

lescence, particularly in the article of diet; but we likewise meet occasionally with cases of acute pleurisy, which, however actively and judiciously treated, inevitably degenerate into the chronic form. M. Broussais, whose opportunities of observation in this matter have been most extensive, states, as the result of his experience, that acute pleurisy passing into the chronic form is decidedly the most frequent cause of empyema. Whenever, therefore, the symptoms of pleuritic inflammation outlast their ordinary period, and are succeeded by those of effusion, we have the strongest evidence of the existence of empyema, inasmuch as the symptoms of empyema make their appearance under those circumstances which most frequently lead to such a termination.

3. *Inflammation of the pleura of so low a type as not to present the ordinary symptoms of acute pleurisy.*—Several physicians of the last century, and particularly Stoll, had remarked that, in many cases of pleurisy, the stitch which commonly attracts attention to the character of the disease, is altogether wanting, and that the insidious mildness of the whole symptoms in the early stage is such as not even to excite any suspicion of a severe affection. This latent form of pleurisy is essentially chronic in its progress. At no period of its course does it present the intense fever, severe pain, or energetic reaction, which characterize an acute disease. It seldom occurs in persons of good constitution, but usually attacks those who have become cachectic from some cause or other, especially persons of a strumous habit.* There are, however, certain exciting causes, which are said to have a peculiar tendency to generate this latent form of pleurisy, amongst which may be enumerated contusions of the chest, wounds of the pleura, the cold stage of ague, and metastasis of rheumatism. These causes, says M. Broussais,† most commonly give rise to pleurisies that are latent in their origin and chronic in their progress. Effusion of puriform matter may likewise take place into the pleura from other causes, and without being preceded by the ordinary symptoms of pleuritic inflammation. A case of latent empyema, consequent on venous inflammation, lately occurred in the Meath Hospital, under the care of Mr. Porter. The patient, a stout young man, in the course of a few days, after having been bled, was seized with symptoms of phlebitis, and diffuse inflammation of the cellular membrane extending along the arm to the axilla. The disease proved fatal, and on dissection, in addition to the morbid appearances of the diseased limb, the pleura of the same side was found to contain several quarts of pus. In this case, no symptom whatever was observed during life to excite any suspicion of the pleura being the seat of disease. We have also known the amputation for white swelling followed in two instances by copious depositions of pus in the pleura, and in neither

† Op. Cit.

case was there any symptom to indicate disease of that membrane. Several similar cases have appeared lately in the French journals of severe operations, especially those for the removal of suppurating parts, being followed by extensive depositions of pus in the interior, and on the surface of different organs.* In these and similar cases, it is probable that the depositions of pus are formed independently of any inflammatory process in the tissue where they are collected, or, to use the expression of M. Andral, "that the pus is first taken into the circulation, and subsequently separated from the circulating fluid, just as mercury, when injected into a vein, is found to deposit its globules in different parts of the body."†

Whatever the cause of the latent character of the disease may be, experience has fully proved that in a considerable proportion of the deaths from empyema, no symptom of pleuritic disease had been observed until the effusion was fully formed; for which reason the diagnosis of this form of empyema is often very obscure.

4. *Pleuritis caused by the introduction of foreign substances.*—Foreign bodies may be introduced into the pleura either through the lung or through the parietes of the chest. Amongst the former may be enumerated the contents of tuberculous, pneumonic, or gangrenous abscesses, or of pulmonary apoplexy bursting through the pleura. Of these the rupture of a tuberculous abscess is beyond all comparison the most frequent in its occurrence. Within the last four years no fewer than eighteen cases of empyema, with pneumothorax from this source, have come under our own observation, fifteen of which were verified on dissection, and we have heard of several other cases occurring in the hospitals of Dublin. The rupture of a pneumonic abscess was supposed, by the older anatomists, to be the most prolific source of empyema; but the researches of modern pathologists have ascertained that the formation of a pneumonic abscess is in itself an exceedingly rare occurrence, and its bursting into the pleura an event still more rare. The rupture of a gangrenous abscess, though of somewhat more frequent occurrence, must nevertheless be considered as an extremely rare cause of empyema. M. Laennec records a case of pleurisy and pneumothorax consequent to the discharge of a gangrenous abscess of the lungs;‡ and he alludes to another case in which a gangrenous eschar made its way into the pleura, determining a pleurisy which lasted fifteen months.§ Andral likewise relates a case of pleuritic effusion produced by the bursting of a gangrenous abscess.|| More commonly, however, the gangrenous affection

proves fatal before sufficient time has been allowed for the formation of empyema. In all these cases, the rupture of the lung and its investing membrane not only pours into the pleural sac the contents of the abscess, but likewise allows the air to enter at each inspiration, (see PNEUMOTHORAX;) and this elastic fluid, by compressing the lung at the same time that it irritates the pleura, produces an effusion which seldom terminates in adhesion, as the lung is, by the surrounding stratum of air, compressed against the spine, and thus prevented from coming in contact with the parietes of the chest. The bursting of pulmonary apoplexy into the pleura has, we believe, only been known to occur in four cases, and in each of these the accident was instantaneously fatal. (See PULMONARY APOPLEXY.)

Various substances may likewise find their way into the pleura through the parietes of the chest, and by their presence give rise to empyema. Abscesses of the liver have been known to burst through the diaphragm into the pleura. A case of this kind is recorded by Morgagni,* and another example of this morbid lesion is detailed in the *Journal de Médecine*.† These may, however, be regarded as very rare cases; for when an hepatic abscess takes this direction, the inflammation which precedes its progress generally produces an adhesion between the lung and diaphragm, which prevents the escape of the matter into the pleura, and directs it into the interior of the lung, from whence it may be expectorated through the bronchi: two specimens, exhibiting this course taken by abscesses of the liver, are preserved in the museum of the Whitworth Hospital. Abscesses formed in the walls of the chest may likewise burst into the pleura, though, like those of the liver, they more frequently open directly into the lung, or point externally, and suppurate on the surface. But in order to obviate the risk of their breaking internally, the safest plan is to make an early opening and let out their contents. The importance of this practical rule is well illustrated in an interesting case related by Dr. Duncan, in the first volume of the *Médecino-Chirurgical Transactions of Edinburgh*, in which the disease having commenced by the formation of an abscess in the parietes of the chest, and no external opening having been made, the pus eroded the pleura costalis, entered the cavity, excited chronic pleuritis, and at last found an exit through the lungs by a bronchial tube, establishing a communication between the aerial passages and the external tumor. Other remarkable examples of the danger of allowing these abscesses to burst internally are recorded by Sabatier;‡ and by De Haen, in his *Ratio Medendi*. Hemorrhage into the thorax from wounded vessels is not unfrequently followed by empyema, and extraneous substances introduced through penetrating wounds of the chest, such as spiculæ

of bone, bullets, pieces of wadding, clothes, &c., by their presence in the pleura give rise to inflammation, which sometimes terminates in empyema, but more frequently in the exudation of organizable matter, which forms an investment round the foreign substance, and limits its effects to the spot where it is immediately situated.*

Such are the principal lesions that usually precede the formation of empyema. We would here observe, that a knowledge of the antecedent disease and of the symptoms preceding the effusion is often as essential towards forming a correct diagnosis of empyema as a knowledge of those symptoms which denote that the effusion has actually taken place, since the distinctive characters of the affection are often more strongly marked during its earlier stages than at its termination. Thus it frequently happens that a patient presents a train of symptoms which may be referred either to hepatization of the lung or effusion into the pleura; and so closely do the symptoms and physical signs of those affections resemble each other, that it is frequently impossible to distinguish between them so long as we confine our attention to the symptoms actually present; but if, on referring to the preceding history of the case, we find that the present symptoms were preceded by those of acute pleurisy subsequently degenerating into the chronic form, the difficulty of diagnosis is at once removed: unfortunately, however, the symptoms which precede effusion are in some cases as obscure as those which attend its actual formation, and hence arises the principal difficulty in detecting the presence of empyema.

Diagnosis.—The diagnosis of empyema has been most materially improved of late years. Laennec's happy application of the principles of mediate auscultation to the diagnosis of thoracic diseases has added a new and valuable set of physical signs to the symptoms of this disease previously known; and the researches of modern pathologists, by reducing those symptoms to their precise signification, and assigning to each its just value as a distinctive character, have rendered the diagnosis of empyema as remarkable for accuracy and precision as it formerly was for error and obscurity.

Of the symptoms hitherto enumerated by nosologists as characteristic of this disease, such as "fixed pain in the chest, breathing laborious but easiest in the erect position, difficult decumbiture on the sound side, fluctuating enlargement of the side affected, and dry tickling cough,"† almost all are common to it with other affections, and even of these equivocal symptoms the greater number are frequently wanting. Under such circumstances it is scarcely to be wondered at if the disease was constantly mistaken, or its very existence overlooked, of which so many examples are

recorded in medical literature that the only difficulty lies in the selection.

From a survey of the recorded cases of empyema and from our own observation, it is evident that, as empyema may exist without its characteristic symptoms, so these symptoms may exist without empyema; of which fact, indeed, the annals of surgery furnish but too convincing proofs in the numerous cases where the operation for empyema has been performed, but where no empyema existed. A remarkable case of this kind is recorded by M. Baffos, in his inaugural dissertation *sur l'Empyème* printed in Paris in 1814. A patient in one of the principal hospitals of that city presented a combination of symptoms which was supposed to demonstrate so unequivocally the presence of empyema that the operation of paracentesis was performed, but to the surprise of the operator no fluid was found; however, as the existence of empyema seemed indisputable, it was resolved in consultation to make an incision into the pleura of the opposite side; the second operation was attended with no better success than the first—not a drop of fluid followed the incision into either pleura. Dionis relates a similar occurrence in the case of the Duke de Montemart, who was operated on for empyema, which he had not; and he mentions another case in which a similar mistake cost the patient his life.* Willis likewise notices the occurrence of such mistakes: "Novi enim (says he) in aliquibus thoracis paracentesin et frustra et non prorsus innoxie celebratam fuisse."†

These examples may serve to show the uncertainty which formerly prevailed in the diagnosis of empyema, and the fatal results which too often followed these errors of diagnosis: it is needless to make any additional observations to point out the great practical importance of the improvements which have lately been made in this department of medical science, by which we are now enabled to detect the existence of this disease in every case where its diagnosis is a matter of practical utility.

The following symptoms and physical signs are those most characteristic of empyema, and when they are all combined, may be considered as quite pathognomonic:—Difficult respiration, increased by motion or exertion of any kind, and considerably aggravated by lying on the sound side; a sense of fulness and oppression in the chest, amounting in some cases to a sense of suffocation; enlargement of the diseased side; protrusion of the intercostal spaces, with obscure sense of fluctuation and œdema of the integuments; dulness of sound on percussion, and absence of the respiratory murmur in the diseased side, which remains perfectly motionless; puerile respiration in the opposite lung, accompanied with violent action of the respiratory muscles; displacement of the heart; descent of the diaphragm and consequent protrusion of the abdomen: to these characteristic marks may be added harassing short cough,

* Sec, on this subject, Hennen's Military Surgery, and Baron Larrey's *Mémoires*.

* Dict. des Sciences Médicales, art. *Empyème*.

† Opera omnia; de *Empyemate*, p. 97.

small rapid pulse, flushed cheeks, and other symptoms of hectic fever.

From this combination of symptoms, especially when they have been preceded by those of inflammation of the pleura, the existence of empyema may be certainly inferred. It is, however, to be remarked, that several of these symptoms vary considerably, according to the extent of the effusion, and even in those cases where the quantity of effusion is the same, according to the date of its formation. Thus, when the effusion is rapidly formed, the difficulty of breathing is extreme, the accompanying fever intensely violent, and the anxiety and dread of suffocation urgent and unceasing; but as the disease continues, these symptoms often assume more of a chronic character; the dyspnoea gradually diminishes, and is perhaps only perceptible after exercise or taking food; the fever likewise disappears, or is only perceptible towards evening; and the patient, encouraged by this abatement of the symptoms, complains only of weakness, and anticipates the speedy restoration of his health and strength. But if the physical signs of the disease be had recourse to, it will be found that this alleviation of symptoms is altogether illusory, and that the disease, instead of receding, has been steadily advancing.

As, then, the most characteristic symptoms of this disease are liable to considerable modification, and as several of them are occasionally wanting altogether, it may be worth while to examine each symptom separately, to consider how it is produced, what it signifies, and what is the precise relation it bears to the disease. We shall thus understand the just value of each, and see how far the existence of empyema is proved in the affirmative by its presence, or in the negative by its absence; for, as it is impossible to describe every variety of combination which the symptoms of empyema may present, the only alternative is to enable the physician, by acquainting him with the precise import of each symptom individually, to form his opinion of their signification collectively in whatever form of combination they may present themselves.

1. *Dyspnoea*.—The difficulty of breathing experienced in this disease is generally proportionate to the degree of pressure which the lung sustains, or, in other words, to the quantity of the effusion. To this general rule there are, however, numerous exceptions; indeed there is scarcely an author who has treated of this disease that does not recount instances of patients labouring under such extensive effusion as to compress the greater portion of one or even of both lungs, whose respiration was nevertheless not in the least affected.* We must not, however, suppose that the aeration of the blood is as perfectly accomplished in those cases as when both lungs are in the free exercise of their functions, for experience has shown that sooner or later these patients lose their flesh and strength, and their lives eventually fall a sacri-

fice to the disease. Experience has shown that the difficulty of breathing is extremely urgent when the empyema is formed rapidly, but that in more chronic cases the dyspnoea is generally proportionate to the violence of the fever, and the quantity of the effusion. Some individuals, however, have their breathing much more easily affected than others, and accordingly, under apparently similar circumstances, the dyspnoea continues extremely urgent in some from the commencement of the disease to its termination; in others, the respiration is at first greatly affected, but the dyspnoea gradually diminishes, and recurs only at intervals when the circulation is excited; whilst, in a third set, the respiration continues apparently unimpeded from the beginning to the end of the disease.* For these reasons, and as, moreover, the symptom of dyspnoea is common to almost every affection of the lungs, it can only be used in the diagnosis of empyema as corroborative of other less equivocal symptoms.

2. *Decumbency*.—The difficulty which patients affected with empyema experience from lying on the sound side has been noticed by all writers on the subject since the time of Hippocrates. The cause of this symptom, which by many is considered as quite pathognomonic, has been differently explained by authors. Le Dran ascribes the sense of suffocation, produced by turning on the side opposite to that in which the collection of pus is situated, to the mediastinum being on a sudden loaded with an unusual weight of fluid.†

M. Richerand, on the other hand, made several experiments, by producing artificial hydrothorax, to prove that fluid contained in one side of the chest could not, by its gravitation, displace the mediastinum, or exert any pressure on the organs contained in the opposite side, and hence argued that the difficulty of lying on the sound side arises not from the pressure of the incumbent fluids, but from the obstruction to the dilatation of the sound side, produced by placing it under the weight of the body.

In opposition, however, to this ingenious reasoning, we have direct proof of the influence of the weight of the fluid; for we find that in cases of pneumothorax with empyema, the patient can generally lie on the sound side so long as the effusion is principally gaseous; but as the proportion of ponderable fluid increases, decumbiture on the sound side becomes impossible. In like manner, in cases of empyema the dyspnoea is in general greatly aggravated by lying on the sound side; but when the fluid is evacuated, the patient is immediately enabled to turn on the sound side, although the necessity for its free dilatation continues as great as before—the diseased being still in a state of perfect inaction. In the case of pneumothorax with empyema, related in the fifth volume of the Dublin Transactions, in which the operation of paracentesis was performed, the patient was enabled to lie on the sound side the night after the fluid was drawn off, though it was ascertained by auscultation that the side was then

* See, for example, *Frank*, de Curand. Hom. Morb. t. viii. p. 232; *Duncan*, Edin. Journ. loc. cit.; *Andral*, op. cit. p. 240.

* *Andral*, op. cit.

† Observations on Surgery, p. iii. edit. 2.

filled with air, and the necessity for the free dilatation of the sound side consequently as great as before the operation.

These observations render it probable that the difficulty of lying on the sound side arises from the load which is thereby thrown on the mediastinum, as well as from the obstruction which the muscles of inspiration experience when the side which they have to dilate is placed under the weight of the body. To avoid this inconvenience, patients labouring under effusion into the chest generally lie on the diseased side, or else on the back, with a slight inclination of the body towards that side. This latter position is the more general of the two, and is so very characteristic as to lead in some cases to a suspicion of the disease even before any farther examination has been made. This position, however, is not so constantly observed but that we meet with frequent deviations from it. When the fever has completely subsided, and the thoracic viscera have become habituated to the pressure of the effusion, the patient can sometimes lie indifferently on his back or on either side; and there are even some cases on record where the patient lay constantly on the sound side. J. F. Isenflam relates a remarkable case of this kind in which a patient presenting all the usual symptoms of empyema lay generally on the right side, which for this reason was supposed to be the seat of the disease. Accordingly the operation was performed, but no pus was found. The patient died, and on dissection it was discovered that the left side was the seat of the empyema.* Morgagni relates a case of this kind, on the authority of Valsalva, and M. Baffos† records another instance. These, however, may be considered as exceptions to a general rule, and probably depend on some adhesions which confine the effusion, and prevent its gravitating to the most dependent part of the chest.

When the empyema is double, the patient can seldom lie in the horizontal position, but remains constantly seated with his body inclined forward.‡

3. *Dilatation of the side.*—When we strip a patient affected with empyema, and examine his chest, we generally perceive a marked difference in the size and shape of the two sides; that into which the effusion has taken place appears considerably larger; and this difference, which is most evident posteriorly, is rendered still more remarkable by the altered position of the ribs, which continue fixed immovably in the position they naturally occupy during full inspiration, and contrast strongly with the increased motion of the ribs of the opposite side. The intercostal spaces are also remarkably wide, and in some cases, especially in thin persons, project beyond the level of the ribs: this latter sign is of considerable importance, as it serves to distinguish empyema from hepatization of the lung or enlargement of the liver.

The increased size of the diseased side is in general very perceptible to the eye when it amounts to five or six lines: it seldom exceeds

an inch and a half; but in Dr. Croker's case, already alluded to as having had seven imperial quarts of pus drawn off at one time, the difference amounted to three inches and a half. The most accurate way of ascertaining whether any and how much dilatation exists, is by measuring both sides with a tape carried from a central point in the sternum under the mamma to the spinous process of the corresponding vertebra. The xiphoid cartilage frequently deviates from the median line, and is therefore an improper point to measure from: it may be also well to observe that the right side of the chest is generally some lines larger than the left, probably from the greater development of the pectoral muscles of that side. Another cause which might lead to erroneous conclusions from the measurement of the thorax is, that in those cases of empyema where absorption takes place to a certain extent, the parietes of the chest fall in as the effusion is removed: in this way the diseased side comes to measure less than the other; and if the thorax were measured for the first time under those circumstances, the sound side would appear comparatively dilated, and might be mistaken for the seat of the disease. This error would, however, be at once rectified on applying the stethoscope. In deformed persons it is impossible to draw any inference from measurement of the thorax, and in fat persons, especially in females, the results are often very unsatisfactory. To sum up—dilatation of the diseased side may be considered as one of the most valuable symptoms of empyema; but it is frequently wanting even in those cases where the effusion amounts to several pints; and as it may proceed from various other causes, such as pneumothorax, emphysema, and enlargement of the liver, so it cannot be relied on as a single symptom, though in combination with others it is a most valuable diagnostic mark of the disease. It should also be recollected that the diameter of the diseased side may be less than that of its fellow in consequence of the partial absorption of the effusion; indeed this case is by no means uncommon.

4. *Edema of the side.*—Edema of the integuments of the diseased side, extending sometimes to the arm and side of the face, is an occasional but by no means a constant symptom of empyema: it sometimes occurs at an early stage of pleurisy, accompanied with pain and tenderness in consequence of the inflammation extending to the superjacent parts, and in some instances does not make its appearance before the last stages of the disease. Purple ecchymosed spots have also been observed on the most dependent part of the thorax. They are said to occur chiefly when the effusion is composed of blood.

5. *Fluctuation.*—This can sometimes be felt, in very thin subjects, through the intercostal muscles. In a patient who was recently operated on in the Richmond Hospital in Dublin, it was very evident. It is one of the least fallible signs of empyema, but yet should not be trusted to exclusively, as abscesses occasionally form in the parietes of the chest, which yield a similar sensation to the finger. In November 1830, a subject was placed on the table in the

* Versuche einer praktischen Abhandlung neber die Knochen. Erlangen, 1782.

† Op. cit.

‡ Andral, op. cit.

dead room of the Whitworth Hospital, with considerable enlargement of the right side, and distinct fluctuation in the intercostal spaces. On removing the integuments, we discovered that both the enlargement and the fluctuation were caused by an enormous abscess of the liver, which had made its way through the diaphragm near its anterior attachment to the ribs, and had thence poured its contents into the cellular tissue which invests the muscles on the side of the chest, and thus produced the sense of fluctuation so distinctly felt between the ribs. A case nearly similar is recorded by Morand, who performed the operation of paracentesis between the third and fourth false ribs, in a case which he supposed to be empyema from the oedema of the integuments and deep-seated fluctuation; but he found to his surprise that the chest was perfectly sound, and that the pus which was situated in front of the pleura came from an abscess in the liver.* We have likewise heard of an encephaloid tumour, projecting between the ribs, having been mistaken for a case of empyema pointing externally, and opened accordingly.

These examples are sufficient to show the importance of carefully examining every symptom of the disease, instead of trusting exclusively to any one sign, however unequivocal it may appear. Fluctuation is much more frequently perceptible through the intercostal spaces when the empyema is circumscribed, than when the fluid is effused into the general sac of the pleura; in the former case it not unfrequently points externally, and by its rupture affords an exit to the encysted matter. When these fluctuating tumours communicate with the bronchi through the substance of the lungs, they usually acquire an emphysematous feel, as in the remarkable case related by Dr. Duncan, in which several tumours of this description were formed over the surface of the diseased side.†

6. *Ægophony*.—The peculiar modification of the voice, termed ægophony, scarcely deserves to be enumerated among the signs of empyema, as it is only heard in those cases of effusion where the fluid interposed between the surface of the lung and the interior of the chest forms a thin layer of only a few lines in thickness. Whenever the effusion exceeds this quantity, the ægophony invariably ceases; and hence it is seldom audible in empyema, where the effusion is generally very extensive, and accumulates in the most dependent part of the chest, instead of forming a thin layer over the surface of the lungs, as in cases of recent pleurisy. Whenever, therefore, ægophony continues to be heard in cases of chronic effusion accompanied with cough, difficulty of breathing, and hectic fever, we may infer with tolerable certainty that the empyema constitutes an inconsiderable part of the disease, and that tubercles, or some other morbid structure, are formed within the chest.

7. *Fluctuation on succussion*.—The sound of fluid splashing within the chest, similar to that

produced by agitating a cask partly filled with water, may sometimes be heard on applying the ear to the chest while the body of the patient is gently shaken. This sound has generally been described as the most pathognomonic sign of empyema, but as it never occurs except when the pleura contains air as well as fluid, it should more properly be considered as a symptom of the empyema being complicated with pneumothorax, and consequently as affording a more unfavourable prognosis, especially where the pneumothorax proceeds, as it most commonly does, from the rupture of a tuberculous abscess in the lung. (See PNEUMOTHORAX.)

8. *Dull sound on percussion*.—When we employ percussion over the chest of an individual labouring under empyema, the difference of sound elicited from the healthy and the diseased side is very striking, the former being clear and hollow, while the latter is as dull as if it were the thigh that had been struck. When the effusion is so extensive as to occupy the whole side of the chest, the sound is perfectly dull all over that side, unless in those parts where the lung is retained in contact with the chest by old adhesions. When the effusion only occupies the lower part of the chest, the dullness of sound is confined to that region; and in cases of circumscribed empyema the dull sound corresponds exactly to the surface of the effusion, if the fluid be in contact with the costal pleura; but when it is confined between the lung and mediastinum or diaphragm, or between two adjoining lobes of the lung, the sound on percussion is seldom appreciably altered, and hence the diagnosis of these affections is often extremely difficult.

9. *Absence of the respiratory sound*.—Over the same extent of surface, and for the same reason that the sound on percussion is rendered dull, the respiratory murmur is totally extinguished. This absence of the natural sound is in general very apparent, and is among the most constant of all the physical signs of empyema. There are, however, some sources of fallacy in the evidence furnished by the state of the respiration in this disease, which it is important to be acquainted with. In some cases where the respiratory murmur is completely extinct, the air still continues to enter the bronchial tubes, though it cannot penetrate into the cells, and thus bronchial respiration may be heard over the situation which the condensed lung occupies; and if the bronchial tubes be obstructed with mucus, the different varieties of mucous rattle may likewise be heard in the same situation. Another circumstance calculated to mislead is, that the puerile respiration of the sound side is sometimes transmitted along the parietes of the diseased side, and may thus lead the auscultator into the erroneous supposition that respiration was going on in the diseased side: this error may in general be avoided by observing that the intensity of the respiratory murmur gradually diminishes as the stethoscope is removed from the sound side; and this criterion will be still farther confirmed by examining the ribs of the

* Richter, Chir. Bibl. t. iv. p. 146.

† Medico-Chirurgical Transactions of Edinburgh, vol. i.

diseased side, which will be found in a state of inaction, if the respiratory murmur be really transmitted from the opposite side. Another source of error, still more calculated to convey a false impression of the true nature of the disease, arises from the lung being retained in contact with the parietes of the chest by old adhesions. In such cases the effusion cannot insinuate itself between the chest and the surface of the lung, so as to compress its substance or mask its sounds; and hence the respiration continues to be heard, more or less plainly, over an extent of surface corresponding to the internal adhesions; most commonly the lung is attached at its upper lobe, more rarely at its lower, and in some instances the attachment extends vertically from the apex to the basis. These extensive adhesions constitute one of the most perplexing obstacles to the detection of this disease. Whenever respiration is suspended in one lung, the other, if free from disease, invariably takes on a compensatory increase of action, and the respiration becomes puerile: this phenomenon is therefore of considerable importance, as it announces the inefficiency of the opposite lung.

10. *Displacement of the heart.*—The science of morbid anatomy furnishes numerous examples of the strongest membranes yielding to the application of constant and gradually increased pressure; in empyema, and likewise in pneumothorax, the mediastinum yields to the distending force of the accumulated fluid, and allows the heart to be displaced by its pressure. When the left side is the seat of the effusion, the heart is thrust from its natural situation, either down into the epigastrium, where it may be seen and felt pulsating, or over to the right of the sternum, where its pulsation is sometimes so strong as to attract the attention of the patient. When the effusion is in the right side, the change in the heart's position is not in general so remarkable; but by careful examination with the stethoscope, it will generally be found to pulsate considerably to the left of its natural situation. In two cases, one of which we have already alluded to as having been lately operated on for empyema, the apex of the heart was distinctly felt striking against the stethoscope between the fourth and fifth ribs in the left axilla.

As, then, displacement of the heart is constantly produced by effusion into either sac of the pleura, and seldom if ever arises from any other cause, it may be considered as the most constant and least equivocal of all the signs of effusion, and, when joined with other symptoms and physical signs of empyema, may be regarded as quite pathognomonic.

11. *Depression of the diaphragm.*—The diaphragm in like manner yields to the pressure of the incumbent fluid, and descends into the abdomen, thrusting the abdominal viscera before it. When the right side of the diaphragm is depressed, the liver is protruded beyond the margin of the ribs, and has even been felt so low as the iliac fossa.* Such cases have re-

peatedly been mistaken for enlargement of the liver. Of this a remarkable instance is recorded by Roux, in a memoir appended to the third volume of Desault's works, where, in a case pronounced by one of the most eminent medical men in Paris to be an incurable enlargement of the liver, the true nature of the disease was discovered by Bichat, who performed the operation of paracentesis thoracis, and thereby saved the patient's life.

12. *Abdominal pressure.*—Another test of the existence of pleuritic effusion imagined by Bichat, and described by Roux in the memoir just quoted, is the effect of pressure on that side of the abdomen where the effusion is suspected to exist. According to those celebrated anatomists, pressure exerted on that side of the abdomen corresponding to the empyema, thrusts the diaphragm and the fluid which rests on it up into the thorax, and thus, by increasing the pressure of the effusion on the lung, produces an insupportable sense of suffocation. In those cases where we have employed this test, the result was the very opposite of that above stated; for while no uneasiness was produced by pressing up the diaphragm into that side where the effusion existed, any attempt to stop the free motion of the diaphragm at the other side, where alone respiration was still carried on, was most distressing to the patient. The same observation has likewise been made by M. Chomel.*

13. *Cough and expectoration.*—The cough in empyema is generally short and single, and when there is no accompanying bronchitis, is often wanting altogether. If there be any expectoration it is generally catarrhal, unless when a communication is established between the bronchi and the fluid effused in the pleura; in which case the quantity of matter expectorated is sometimes so great as to threaten suffocation. This, however, can only occur when a large communication is suddenly formed and opens directly into one of the principal bronchi; but in those cases where the rupture is small and communicates only with the lesser bronchi, the evacuation of the fluid must go on slowly and by small quantities at a time. In such cases it is often difficult to determine the source of the expectoration: some writers describe it as possessing a peculiar fetor which is quite characteristic. Laennec compares the smell to that of gangrene.† Professor Nespoli to the smell of assafoetida, "ma assai più di questa penetrante e acido."‡ Some have compared this odour to garlic, some to that of phosphoretted hydrogen, and others to other ill smells.§ But as these fetid smells have all been observed in the expectoration of gangrene, and even of simple bronchitis, too much importance should not be attached to this sign; more particularly as in many cases of fistulous communication between the pleura and bronchi no such fetor has been observed. When, however, this appearance of the expectoration is

§ Dr. Forbes's Note to Laennec, p. 447.

* Stoll, Ratio Medendi.

accompanied with a marked improvement of other symptoms, and with a diminution in the diameter of the dilated side, we may conclude that a communication with the bronchi has been formed; and this diagnosis will be still farther confirmed if the signs of pneumothorax supervene in consequence of the atmospheric air entering through the communication.

14. *Fever*.—The febrile symptoms which accompany this disease vary considerably, according to the constitution of the individual and the progress of the effusion: thus, while acute empyema is usually accompanied with rapid pulse, burning heat of skin, and other symptoms of the highest degree of febrile excitement, the more chronic forms of the disease often present no other symptom of fever than a slight acceleration of the pulse towards evening, or after taking food; and the patients sometimes even enjoy a state of perfect apyrexia.

It has been remarked by Broussais, and the observation has been confirmed by Andral, that the hectic of empyema is never accompanied with profuse night-sweats, unless when tubercles are developed in the lungs or in the false membranes of the pleura. Another peculiarity in the hectic of empyema, according to Broussais, is, that the pulse generally returns to its natural frequency after rest, particularly after a night's rest; whereas, in the hectic of phthisis, the pulse seldom or never comes down to its natural standard. The same author likewise states that in the hectic of empyema there is seldom any flushing of the cheeks, unless when the difficulty of breathing is very great, in which case the face and lips present a bluish tint and congested appearance, arising no doubt from the deficient aeration of the blood; whereas in phthisis the circumscribed flushing of the cheeks contrasts strongly with the marked paleness of the rest of the countenance. Whenever, therefore, the hectic fever of empyema presents the symptoms just described as appertaining to the hectic of phthisis, we may conclude that the effusion is probably complicated with tubercles in the lungs, or in the false membranes of the pleura.

From these observations it appears, that although there is no one symptom or physical sign which, taken singly, can be considered as pathognomonic; yet, from the combination of these symptoms with the physical signs derived from auscultation and percussion, the presence of empyema may be inferred almost with certainty. It must however be admitted that we occasionally meet with cases in practice in which it is extremely difficult to ascertain the existence of effusion. This difficulty, in some instances, depends on symptoms being present which appear incompatible with the presence of effusion, and in others on the only symptoms present being common to empyema with other affections, and consequently insufficient to decide the true nature of the disease.

To the former class belong those cases of empyema in which the lung is extensively attached to the costal pleura, and those of circumscribed effusion situated in the interior

or bottom of the chest; in both of which cases, contrary to what usually occurs in empyema, the respiration continues audible, and the sound on percussion is little if at all affected. The diagnosis of these cases has already been the subject of consideration.

The diseases which from the similarity of their general symptoms and stethoscopic phenomena are most liable to be confounded in practice with empyema, are tubercular consumption, hepatization of the lung, the development of morbid growths in the pleura, and, when the disease is at the right side, enlargement of the liver.

We shall now offer a few remarks on the distinctive characters of these different affections.

1. *Tubercular consumption*.—The general symptoms of phthisis and empyema are sometimes so precisely similar as to have deceived even the most experienced practitioners. The stethoscopic phenomena of these diseases are, however, so very characteristic, that it is scarcely possible now to confound them. In the first stage of phthisis, when the tubercles are in their crude state, the respiratory murmur is seldom if ever so completely suppressed as in empyema. In the former disease the absence of respiration first commences, and is always most marked, in the upper lobe, and in the latter in the lower lobe. At a more advanced stage, when the tubercles are softened, the characteristic signs of pectoriloquy, mucous râle, and gurgling cough, at once point out the true nature of the disease, and prevent the possibility of mistaking it for empyema.

2. *Hepatization of the lung*.—Owing to the similarity of the stethoscopic phenomena which hepatization presents, it is much more likely to be confounded with empyema. The following signs will, however, seldom fail to enable the physician to distinguish these diseases. In hepatization the antecedent symptoms are those of the first stage of pneumonia, and the cough is usually attended with characteristic viscid sputa; the respiration is never totally suppressed, but its place is supplied by strong bronchial respiration and resonance of the voice; the side is never enlarged; the intercostal spaces are never protruded; and the heart is never displaced; either of these symptoms occurring will, therefore, at once decide in favour of empyema. To these distinctive characters we may add that chronic empyema is, comparatively speaking, a disease of common occurrence; whereas chronic hepatization is an affection so rare, that Laennec commences his chapter on the subject by questioning the reality of its existence. This opinion is confirmed by the experience of Andral, who states* that of one hundred and twelve cases of pneumonia treated in La Charité, only one exceeded thirty days, or could be regarded in the light of a chronic disease. Chomel and Louis likewise concur in describing chronic peripneumony as one of the rarest forms of pulmonary disease.

3. *Tumours in the sac of the pleura*.—The same remark is likewise applicable to the de-

* Op. cit.

velopment of those tumours in the pleura which compress the lung and occupy its place. A remarkable case of this kind is related by Corvisart in the "Bulletins de la Faculté de Médecine." The patient's symptoms were such as to lead this accurate observer into the belief that the disease was empyema; but, on dissection, he was surprised to find instead of pus a solid substance answering to Laennec's description of encephaloïde, occupying the entire of the left side, the lung having, as he describes it, totally disappeared. An analogous case is recorded by Boerhaave, as occurring in the person of the Marquis de St. Auban.* M. Reclamier found in the body of a patient whom he considered as affected with empyema, one side of the chest entirely filled with a mass of tuberculous matter. A still more remarkable example of this disease is recorded by Laennec,† to whom it was communicated by M. Cazol.

4. *Enlarged liver.*—The last disease which we shall enumerate as liable to be confounded with empyema is enlargement of the liver. This viscus is sometimes so much increased in size as to ascend into the thorax, and compress the lung into the upper and back part of the chest. In such cases the sound on percussion is as completely dull, and the respiratory murmur as perfectly extinct, as in empyema. Neither is the diagnosis always facilitated by referring to the earlier symptoms of the disease, as empyema is often ushered in with the same dull pain in the hypochondrium that usually attends hepatic disease; and the projection of the liver beyond the margin of the ribs may proceed either from enlargement of that organ, or from its being thrust down by the pressure of the superincumbent fluid. Such are the principal points of similitude between these diseases, which have frequently imposed on the most experienced practitioners, but which it is of the greatest importance to distinguish, as is exemplified in the case already quoted from the memoir published by Roux, where the life of the patient supposed to be labouring under incurable disease of the liver was saved by the operation for empyema, which the accurate discernment of Bichat discovered to be the real disease. It is only necessary to allude here to the possibility of mistaking these diseases one for the other, as it seldom happens that their diagnosis is not rendered sufficiently easy by the presence of some unequivocal symptom, either of hepatic disease or of empyema.

Prognosis of empyema.—The prognosis in this disease is generally unfavourable, as by far the greater number of cases terminate fatally, whatever treatment is adopted. But as empyema is more properly the termination of a pre-existing disease than a primary or specific affection, it is impossible to form a correct prognosis of its probable termination in any given case without taking into consideration the character of the pre-existing disease and the condition of the lung and pleura, as well

as the amount of the effusion and the possibility of its removal; for on these circumstances the issue of the case principally depends. Thus, for example, while the empyema produced by the rupture of a tuberculous abscess in the lung has never, as we believe, been known to terminate otherwise than in death, the empyema which succeeds to penetrating wounds of the chest has in a great number of cases terminated favourably.* In the former case the effusion is produced by, and complicated with an incurable affection of the lung, while in the latter it is unconnected with any organic disease of the thoracic viscera.

In acute empyema, when the effusion increases rapidly, and is accompanied with great difficulty of breathing and febrile excitement, the disease may prove fatal by suffocation during the acute stage, or, as more frequently happens, may degenerate into the chronic form.

In chronic empyema, whether proceeding from acute or chronic pleurisy, the termination of the disease, when abandoned to the resources of nature, is almost invariably fatal; though, if we could place implicit confidence in the representations of the older writers, it would appear by no means uncommon that it should terminate by absorption, or even by critical evacuation. Billard states that a case of empyema, on which he was on the point of operating, terminated favourably by a critical sweat, produced and kept up by the internal use of the acetate of ammonia, which he therefore recommends as a most efficacious remedy in this disease.† The effusion of empyema has also been stated to have passed off, by metastasis, from the intestinal canal, from the bladder, from the vagina; and is said in one instance to have vanished on the eruption of a scabies.‡ Dr. Darwin relates the following extraordinary instance of recovery from this disease:—A servant man, after a violent peripneumony, was seized with symptoms of empyema, and it was determined after some time to perform the operation: this was explained to him, and the usual means were employed by his friends to encourage him, by advising him "not to be afraid," by which good advice he conceived so much fear that he ran away early next morning, and returned in about a week *quite well*. Without, however, incurring the imputation of scepticism, we may perhaps be permitted to doubt the accuracy of these observations, and to question whether the disease thus marvellously cured had ever existed, especially as we have seen how very inadequate the means of ascertaining the existence of the disease were in those days.

Of eighteen cases of chronic pleurisy recorded by Broussais in his "Histoire des Phlegmasies Chroniques," only one ultimately recovered. Laennec likewise states that the disease has seldom any natural tendency

* See Baron Larrey's Mémoire sur les effets de l'opération de l'empyème, Chirurgie Militaire.

† Dictionnaire des Sciences Médicales, Art. *Empyème*.

* Zimmerman, Traité de l'Expérience.

† Op. cit.

towards resolution, and this statement has been so fully confirmed by the experience of modern physicians, that doubts are now very generally entertained whether the fluid is ever removed by absorption in cases of genuine empyema; and, accordingly, it has been recommended on high authority, that the operation of paracentesis should be performed as soon as ever the presence of empyema can be ascertained with certainty. "In tali casu," says Willis, "pharmacia haud multum opus erit, sed tantum corpore preparato illico ad lateris apertione procedatur."^{*}

But although the instances of recovery from this disease by the absorption of the effusion are not sufficiently numerous to inspire us with much confidence in the efficacy of the remedies usually employed for that purpose, still there are a sufficient number of well authenticated facts to prove the possibility of the disease terminating in this favourable manner, and, consequently, to establish the propriety of trying the effect of appropriate remedies before having recourse to the operation, unless in those cases where the effusion is so extensive as to preclude all reasonable prospect of its absorption, or the symptoms of suffocation so urgent as to require the immediate evacuation of the fluid.

Treatment.—In order to promote the resolution of this disease, the first object of medical treatment should be to moderate any febrile excitement which may arise, as experience has fully proved that a state of perfect apyrexia is the most favourable condition for the absorption of the effusion; for this purpose it is seldom necessary to have recourse to general blood-letting, unless in cases of internal hemorrhage. Cupping over the part or leeches may occasionally be applied with advantage when an exacerbation of the pain and other symptoms indicate the supervention of a fresh attack of inflammation on the diseased surface; but a rigid enforcement of the antiphlogistic regimen will be found the most effectual method of subduing the fever. "This point is of such paramount importance," says M. Broussais, "that I regard it as the basis of the treatment in all those chronic affections of the chest which are sufficiently violent to excite fever; indeed, the physician cannot be too strongly impressed with the idea that, so long as any fever continues, the more his patient eats the shorter time he lives, and that by lowering his diet he will take a more prompt and effectual method of removing the febrile paroxysms than by repeated bleedings, or by covering his chest with blisters."[†] These observations are particularly applicable to those paroxysms of fever which supervene during the course of chronic pleurisy: for so long as they continue, any attempt to repair the strength by the use of nutritious diet will only aggravate the fever and increase the consequent debility. When, however, the fever subsides, it is of the greatest importance to support the patient's strength by the use of light nutritious diet, and even by

the administration of tonics and stimuli when required, taking care, however, to avoid pushing the tonic treatment so far as to reproduce fever. At the same time, the absorption of the fluid may be promoted by increasing those natural discharges of which nature sometimes avails herself, as of so many emunctories, for the evacuation of internal suppurations, and by exciting artificial discharges from the surface by the use of counter-irritants and derivatives.

Purgatives, according to Laennec, to be useful, ought to be pretty frequently repeated. They are particularly indicated subsequently to bloodletting, when the abundance of the effusion, or the rapidity of its formation, and the general symptoms give reason to presume that the pleurisy is hemorrhagic.

On the same authority, diuretics are said to have no evident effect upon the absorption unless they are given in larger doses than is customary. He was in the habit of carrying the acetate of potash to the extent of six drachms or even of two ounces in the day, and gave nitre in doses of from forty grains to three or four drachms if the patient bore it well. With this latter Laennec sometimes combined sal ammoniac, according to the method of Triller, and also gave with advantage the extract of squills, as recommended by Quarin, in a minimum dose of two grains every three hours.^{*}

Diaphoretics and expectorants have likewise been found serviceable in some instances, and may therefore deserve a trial, especially in those cases where the efforts of nature manifest any tendency to produce a critical evacuation by diaphoresis or expectoration, in which case the propriety of promoting the discharge established by nature is manifestly indicated.

So long as any fever is present, counter-irritants of any kind should be employed with the greatest caution; but when the febrile symptoms subside, a large blister may be applied with advantage over the affected side, and kept open for several days, provided it does not produce much constitutional irritation. If the effusion does not diminish under this treatment, it will be advisable to heal the blistered surface and try the effect of a different kind of counter-irritant; for this purpose setons or caustic issues may be used, but, in order to produce any decided effect, they should be kept discharging for a considerable length of time. The use of the moxa is strongly recommended by Baron Larrey, who states that he has seen it act most beneficially as a revulsive in several cases of empyema.[†] The actual cautery is another powerful revulsive, which was much employed by the older surgeons, who seem to have frequently had recourse to it with decided benefit as a means of establishing a counter-irritation and derivation from the diseased pleura.

There is another mode in which the efforts of nature occasionally effect a cure in this disease, namely, by the formation of a fistulous

^{*} De Empyemate, p. 97.

[†] Phlegmasies Chroniques, vol. i. p. 355.

^{*} Dr. Forbes's Translation of Laennec, p. 473.

[†] See Observations sur les Effets de Moxa, in the Journal Complémentaire, tom. v.

passage through the lungs or through the walls of the chest, which serves as an outlet to evacuate the matter contained within the pleura. This spontaneous evacuation of the matter of empyema occurs chiefly, if not exclusively, in those cases where the empyema is circumscribed, and the fluid is prevented from escaping laterally by adhesions. When no such adhesions exist, the fluid having full liberty to accumulate within the chest, seldom points externally; and, accordingly, it is extremely rare to find any appearance of erosion or ulceration in the costal or pulmonary pleura when the effusion occupies the general sac of the pleura, though such appearances are by no means uncommon when the effusion is circumscribed.

Laennec states that the spontaneous evacuation of the matter of empyema is more frequently effected by rupture into the bronchi than by ulceration through the walls of the chest; but in comparing the records of those cases which have been published in this country as well as in France, it appears that their comparative frequency is pretty nearly equal.

When the matter bursts into the bronchi, the communication is generally formed by the detachment of a gangrenous eschar, or by erosion and ulceration of the pleura and pulmonary substance. The passage thus formed is usually lined with an adventitious membrane, which prevents the matter from infiltrating the tissue of the lung, and conducts it directly into the bronchi, from whence it is subsequently removed by expectoration. Many instances of this mode of the escape of pus are on record. Dr. Forbes met with a case of this kind, and has had several undoubted instances related to him by practitioners.* Broussais gives two cases of gangrenous perforation of the pleura pulmonalis, and another in which the communication seems to have taken place from simple ulceration. Le Dran met with four cases in which the disease terminated in this way. A case of rupture of a circumscribed empyema into the bronchi, followed by a copious expectoration of fetid matter, lately fell under the observation of the writer of this article. Laennec also has seen the effusion of chronic pleurisy burst into the bronchi, and Andral observed a similar occurrence in a case of acute empyema. Several other cases may likewise be found in the periodical literature of this country.

When the empyema is about to make its way outwards through the parietes of the chest, the escape of the matter is usually preceded by the appearance of a soft, doughy, inelastic swelling of the integuments, which generally advances in the course of a few days so as to form a distinct fluctuating tumour, and either breaks spontaneously, or else requires an artificial opening to be made through the integuments, in order to give issue to the matter contained underneath. This ulcerative process generally commences in the costal pleura or in the false membranes with which it is lined, and passes in succession through the superincum-

bent parts; sometimes, however, it commences by the formation of an abscess in the walls of the chest, which, bursting both externally and internally, forms a fistulous passage for the escape of the contained fluid. Instances of this termination of empyema are to be found in the writings of almost every author who has treated of this subject. Andral gives three cases in which the matter made its way through the intercostal spaces, and a fourth in which it perforated the diaphragm. Several similar cases are recorded in Le Dran's observations, and in other works on surgery.

The escape of the matter either through the bronchi or through the walls of the chest is generally followed by immediate relief of all the most urgent symptoms, and in some cases the fistulous passage soon ceases to discharge, and cicatrizes; but in other instances the fistula remains open for several months, or even years, and continues to discharge a greater or less quantity of matter, until the suppurating surface gradually diminishes, and becomes at length obliterated by the cohesion of the walls of the abscess. Sometimes, however, the evacuation of the matter, so far from producing any alleviation of the symptoms, seems only to aggravate the disease and accelerate its fatal termination.*

In some cases the formation of one outlet is followed by the formation of several others in succession, as in a remarkable instance published by Dr. Duncan, in the 28th volume of the Edinburgh Medical Journal. A still more remarkable case of this kind is related by Dr. Betty, in the London Medical Repository for March, 1823.

This successive formation of several outlets for the evacuation of the matter of empyema occurs chiefly in those cases where the matter is confined in distinct compartments, having no communication one with the other, and, consequently, requiring each a separate outlet for the evacuation of its contents. A second orifice is also occasionally required when the outlet first formed is situated in the upper part of the chest; for in such cases that portion of the fluid which stands below the bed of the outlet has no means of escaping unless by the formation of another passage in a more dependent situation.

Paracentesis.—When, however, as too often happens in this disease, there exists no reasonable prospect of the effusion being removed by absorption, or evacuated by the efforts of nature, there yet remains the alternative of making an opening into the chest, and thus creating an artificial outlet for the discharge of the matter. This constitutes the operation of *paracentesis thoracis*, or, as it is sometimes called, the operation of empyema.

This operation is at all times easy of execution, productive of little pain to the patient, generally followed by immediate relief, and has in numerous instances been crowned with complete success. Sprengel, in his erudite work on the history of medicine, enumerates

* Op. cit.

* See the seventeenth case in the second volume of Andral's Clinique Médicale.

amongst the advocates of this operation the names of almost all the most distinguished medical and surgical writers, from Hippocrates downwards, many of whom from their writings appear to have practised this operation with a degree of confidence and success unknown at the present day. The same work likewise contains brief notices of such a vast number of cases in which the result was favourable, as are more than fully sufficient to establish the frequent success of this operation.

If, however, we reflect that emphyema is generally the effect of a pre-existing disease of the lungs or pleura, and that the effect of the operation is merely to remove the effused fluid, while the disease of the solids still remains behind, we must be prepared to expect that this operation should often fail of success.

Another cause of the failure of this operation is the condensed condition of the lung, which, from long compression, has lost its expansibility and elasticity. In consequence of this it slowly regains its natural dimensions; and in some cases the unfolding of the lung is still further opposed by the formation of false membranes on its surface. The space thus left between the lung and the walls of the chest by the evacuation of the fluid is filled with atmospheric air, which rushes in through the wound, and excites a purulent discharge so copious as to exhaust the patient's strength, while the inflammation it causes in the suppurating surface cannot produce the obliteration of the cavity, the parts being still too far apart to be agglutinated.

It sometimes happens, also, that the operation is followed by the decomposition of the matter discharged from the wound, which assumes a dark ichorous appearance, and exhales an odour insupportably fetid. This alteration in the sensible qualities of the secretion is generally attributed to the irritating effects of the atmosphere on the imperfectly organized membranes with which the pleura is lined.

These considerations should certainly make us cautious in having recourse to the operation so long as there remained a reasonable prospect of the fluid being removed by other means, but should not deter us from the practice in those cases where other remedies had been tried and found ineffectual, or where the urgency of the symptoms precluded all reasonable prospect of relief from their use. In such cases the sooner the operation is had recourse to the better, for, as Willis tritely observes, "*dummodo vires constabunt præstat remedium anceps experiri quam nullum.*"* Our greatest modern authority on the subject of pulmonary diseases, Laennec, was a great advocate for the performance of the operation.†

Notwithstanding these strong attestations in its favour, the operation has latterly fallen very much into disuse, as much perhaps from the uncertainty of the signs of emphyema as from any experience of its general inutility or danger. Now, however, that the diagnosis of this disease no longer presents the same difficulties

as it did formerly, and that we are enabled to recognize at any early period of their progress, those cases which may be benefited by the operation, and thereby have it in our power to operate early and consequently with better chance of success, it is probable that the operation will be employed more frequently and more successfully than it has hitherto been.* Within the last year the operation has been

* We learn that in London the operation has been repeatedly performed, more particularly under the direction of Dr. Thomas Davies. For the following tabular view we are indebted to the kindness of that intelligent physician, by whose advice the operations were performed. Dr. Davies has requested us to state that five of the cases belonged to Dr. B. Babington and one to Dr. Stroud; Dr. Davies was only called into consultation by these gentlemen.

Notes by Dr. Davies.—1. The result of the operation in the cases of emphyema is very satisfactory; eight of the patients out of ten having recovered. Of these, five were under six years of age, one was between eighteen and nineteen, and two were above twenty-five.

2. All the cases of pneumothorax were complicated with tubercular diseases of the lungs, a circumstance which, of itself, precluded a favourable result. All the patients were beyond twenty years of age.

3. All the cases of hydrothorax were the consequences of disease of the heart. Although none of the patients recovered, they were all relieved by the operation for a considerable time.—EDITORS.

* De Emphyemate, p. 97.

† See Translation, p. 191.

twice performed by the advice of Dr. Marsh, of Dublin, and in both instances the success of the operation has been complete. Dr. Crampton, and Mr. Crampton, the surgeon-general of Ireland, have also communicated to the writer the particulars of three cases from their practice in which the operation was equally successful.

The result of these cases is highly favourable to the more general adoption of the practice, and fully confirms the observation of a modern author, "that it is a measure which has frequently proved successful, and that too in a disease which is generally, if not always, beyond the influence of medicine and too often beyond the power of nature to remove."^{*}

There are two cases in which this operation is particularly indicated:—1. In acute empyema, when the breathing is extremely oppressed, and the effusion goes on rapidly increasing. In this form of the disease, however, it is always advisable, if possible, to defer the operation until the inflammatory symptoms shall have subsided, as it will be of little advantage to evacuate the contents of the pleura so long as that membrane continues in such a state of inflammation as to re-produce the effusion. When, however, the difficulty of breathing is so great as to render the immediate performance of the operation necessary in order to prevent the risk of suffocation, it is probable that this object may be sufficiently attained by making small punctures with a trochar from time to time, when the breathing becomes much oppressed, and drawing off only so much fluid as is necessary to diminish the pressure exercised by the effusion on the opposite lung. By operating in this way the breathing will be immediately relieved, and the danger avoided of admitting the atmospheric air into contact with an already highly inflamed pleura. Perhaps, too, this partial abstraction of the effusion may at once aid the absorption and accelerate the conversion of the false membranes; such, at least, is the opinion of Laennec.[†]

When acute empyema succeeds to penetrating wounds of the chest, it is advisable not to operate before the orifices of the wounded vessels are so firmly closed as to prevent any danger of a recurrence of hemorrhage; for this reason Baron Larrey recommends that the operation should not be performed in such cases before the seventh, or deferred after the eleventh, or, at farthest, the fourteenth day.

2. The second case in which this operation is particularly indicated is in those cases of chronic empyema where the ordinary means for promoting absorption have been tried and found ineffectual. In such cases it is impossible to lay down any general rule as to the precise period at which the operation should be performed, as that point must be determined by the state of the constitution, the urgency of the symptoms, and the extent of the effusion, rather than by the date of its formation. So

long as any reasonable prospect can be entertained of the disease being removed by the efforts of nature, or the influence of medicine, the effects of remedies should of course be tried, but at the same time it should be borne in mind that this disease is generally, if not always, beyond the power of medicine to relieve, and that the persisting in the employment of remedies which experience has so often proved ineffectual, can only tend to diminish the ultimate chance of success by deferring the operation, as is too often done, until the effusion becomes so extensive and the patient's strength and constitution so exhausted as almost to preclude the possibility of recovery.

It has been proved by experience that the operation is frequently successful when the patient is young and of good constitution, the effusion moderate in quantity, recently formed, and unaccompanied with organic disease of the lungs. On the other hand, the prospect of success diminishes considerably when the effusion is very extensive, of long standing, and accompanied by symptoms of confirmed hectic.

The copiousness of the effusion, however, though it generally diminishes the chances of recovery, does not necessarily preclude the success of the operation. Baron Larrey operated successfully in a case where the effusion amounted to fifteen pints; Dr. Hawthorne's patient lost twenty pints of pus during the first twenty-four hours; and in Dr. Archer's successful case, already quoted, eleven pints of fluid were drawn off at the first evacuation. The same remark is likewise applicable to the length of time during which the empyema has existed, and to the symptoms of hectic with which it is accompanied, as there are several cases on record where the operation was successfully performed under those unfavourable circumstances.*

In the numerous class of cases where empyema is complicated with pneumothorax from the rupture of a tuberculous abscess in the lung, the chance of any permanent advantage from the operation must necessarily be very small, in consequence of the incurable nature of the original disease: in such cases, indeed, little else can be hoped for from the removal of the effusion than a temporary alleviation of suffering, or the prolongation of existence for a few weeks or months at the utmost; such at least is the conclusion that we have formed, after having witnessed the progress and fatal termination of eighteen cases of this nature, in five of which the operation was performed with no better success than that just described. (See PNEUMOTHORAX.) Laennec, however, is of opinion that "we must not abandon all hope of cure even when there exists so serious a complication as this, provided there be no evidence of cavities in the opposite lung."[†]

The complication of pneumothorax does not seem to form so serious an objection to the

* Forbes's Original Cases, &c. p. 258.

* Dictionnaire des Sciences Médicales, art. *Empyème*.

† Op. cit.

operation, when not coupled with the presence of tuberculous abscesses in the lungs, as appears from its having been successfully performed in several cases where the sound of fluctuation, audible in the chest, sufficiently proved the coexistence of a gaseous and liquid effusion. Dr. Archer's remarkable case of this kind, published in the Transactions of the Association, has already been alluded to. A still more remarkable case of empyema with pneumothorax, terminating successfully by operation, is related by Dr. G. Hawthorne, in the Edinburgh Medical and Surgical Journal, No. 61.

Neither does the existence of a fistulous passage through the lung necessarily preclude the success of the operation, as is evident from those cases where it was performed after the empyema had burst internally into the bronchi, and yet the communication thus formed through the lung did not appear in the least to impede the patient's ultimate recovery. Le Dran relates a case on which he operated for empyema where "the injection of a small quantity of mel rosarum and barley-water through the wound excited coughing, and part of it passed off by the mouth, mixed with pus;" thus clearly proving the existence of a fistulous passage through the lung, notwithstanding which the patient recovered completely. Several similar cases are quoted in the Dictionnaire des Sciences Médicales, from the writings of M.M. Jaymes, Robin, and Bacqua. In these cases, however, the empyema must in all probability have been circumscribed, and the lung retained by adhesions in contact with the walls of the chest around the circumference of the wound; or else the injection, instead of entering the lung, would have fallen to the bottom of the pleura.

It is unnecessary here to enter into any minute description of the mode of performing the operation, as this is described in all treatises on the subject and in all systems of surgery; but the reader is more particularly referred to the works of Le Dran, Richter, Sharp, C. Bell, Larrey, and Boyer, where he will find all the necessary information.

Authors make a distinction in the operation according as the matter points externally or not. The former they term the *operation of necessity*, from its site being necessarily fixed; and the latter the *operation of election*, from the surgeon being at liberty to select at what part of the chest he makes his incision.

In the empyema of necessity, as it is termed, when the matter points externally, the sooner an incision is made into the tumour the better, as there is no chance of the matter being removed by absorption, and the consequence of delaying the operation has too often been the formation of long sinuous passages through the parietes of the chest and abdomen, and caries of the ribs. Indeed this operation is much more generally successful than that performed at the place of election, which no doubt arises from the circumstance that those empyemas which point externally are almost invariably

circumscribed, and confined to a small extent of the pleural sac.

When no tumour appears, to fix the site of the operation, the place of election generally recommended by surgeons in this country is between the sixth and seventh true ribs, where the indigitations of the serratus major anticus muscle meet those of the obliquus externus. Laennec prefers the space between the fifth and sixth ribs. "Many reasons (he says) point out this spot as the best suited for the operation: for instance, we know that the upper lobe adheres to the ribs more frequently than any other part of the lungs, and that the lower lobe is frequently attached to the diaphragm, while adhesions very seldom exist at the central part of the chest; and even should there chance to be any old adhesions in this point, they may be readily and certainly discovered by some remains of respiration over their site, and the place of the operation may then be varied accordingly: besides we know that the thickest false membranes exist at the junction of the diaphragm with the walls of the chest, and that at the right side an enlarged liver frequently reaches as high as the sixth or even as the fifth rib;" in which case, when the operation is performed in the usual situation, the instrument, instead of entering the chest, would transfix the diaphragm and penetrate the abdomen; there are several cases on record of the operation having been frustrated by this accident. Laennec informs us that in a case of pleuro-pneumothorax, after making an incision through the integuments between the fifth and sixth ribs, he thrust the trochar, as he thought, into the thorax, and was much surprised to find that no fluid followed its introduction; but on dissection he discovered that the instrument had entered the cavity of the abdomen, after transfixing the diaphragm, which had been thrust up into the chest by an enlargement of the liver, and had contracted a firm adhesion to the seventh rib.* A similar accident happened to La Motte;† and Solingen saw the diaphragm wounded by the introduction of a canula after the operation, which was performed between the first and second of the false ribs.‡ The only object of operating so low down is to make the opening at the most dependent part of the chest for the more complete evacuation of the effusion; but this object may be sufficiently attained by operating between the fifth and sixth ribs, which may in fact be made the most dependent point of the chest, by causing the patient to lie, as he generally feels disposed to do, on the diseased side. The danger of wounding the intercostal artery may be avoided by making the incision close to the superior edge of the lower rib.

When the incision is carried through the parietes of the chest and the false membranes with which they may be coated, a rush of fluid

* Op. cit.

† Traité complet de Chirurgie, vol. ii. obs. 77, p. 292.

‡ Handgriffe der Wundarznei, Th. ii. Kap. i. p. 175.

is immediately expelled by the pressure of the parietes, and continues to flow in an uninterrupted stream until the surface of the fluid falls to the level of the wound, after which it issues in a series of interrupted jets corresponding to the motions of the diaphragm; for as this muscle descends in inspiration, the fluid which lies on its surface sinks along with it, and the atmospheric air rushes in to fill up the space created by its descent: again, as the diaphragm rises in expiration, the incumbent fluid is elevated to the level of the orifice, and issues in a jet from the wound; this alternate sucking in of air and expulsion of fluid continues until the quantity of matter is diminished so as no longer to rise to the level of the wound during expiration, after which each movement of the diaphragm is followed by the alternate introduction and expulsion of air, so long as the wound is allowed to remain open. Many reasons, however, render it inexpedient to continue the operation to this period. The sudden removal of so large a quantity of fluid frequently produces such a shock to the nervous system as throws the patient into an alarming state of collapse; the withdrawing so great a degree of pressure from the heart and large bloodvessels and from the opposite lung must likewise derange materially the functions of these important organs, and consequently oppose the success of the operation; and another injurious consequence of protracting the operation until all the fluid has been evacuated is that the parietes of the chest are unable to accommodate themselves to the space which is thus left unoccupied, and which must consequently be filled with atmospheric air.

For these reasons, it is advisable to close the wound before the fluid begins to issue in an interrupted stream, and to repeat the evacuation at longer or shorter intervals, according to the extent of the effusion and the urgency of the symptoms. In general, the removal of twenty ounces of fluid at a time will be found sufficient to relieve the breathing, (as this effect is produced, at least in the first instance, by diminishing the pressure on the opposite lung, and not by restoring the functions of the organ at the diseased side,) and an interval of forty-eight hours may be allowed to elapse before the wound is again opened. When, however, the effusion is very extensive, and the breathing not sufficiently relieved by the removal of the quantity above specified, the fluid may be allowed to flow for some time longer, or the evacuation may be repeated at shorter intervals. When the principal part of the effusion has been removed in this way, a large poultice may be applied over the wound, and the remainder of the fluid allowed to escape as fast as it is secreted.

By this method of gradually removing the effusion we diminish the shock to the nervous system, relieve the thoracic viscera gradually from the pressure of the accumulated fluid, and prevent the introduction of air into the thorax, until the parietes have had time to accommodate themselves to the diminished volume of

their contents, and by their mutual approximation diminish, to the utmost, the space left by the evacuation of the effusion.

The following measurements taken from a patient of twelve years old, who lately underwent this operation, will serve to illustrate the diminution which takes place in the capacity of the diseased side by the falling in of its osseous parietes:—

	Circumference of the diseased side.		Circumference of the sound side.	
	In.	Lns.	In.	Lns.
Immediately before the operation	16	6....	14	1
Evening after the operation	16	3....	14	1
6th day after the operation	14	10....	14	1
7th day after the operation	14	6....	14	1
8th day after the operation	14	5....	14	1
9th day after the operation	13	9....	14	1

Thus, in the space of nine days, the circumference of the diseased side diminished nearly three inches. This contraction of the osseous parietes, aided by the ascent of the diaphragm, and the protrusion of the mediastinum from the increased dilatation of the opposite lung, reduce the cavity of the diseased side to so small a compass, especially in young subjects, whose ribs are susceptible of a much greater degree of motion than those whose cartilages are ossified, as to leave very little space unoccupied for the reception of air. This space is subsequently filled up as the lung gradually expands and rises into contact with its parietes: this, however, is always a very slow process, as several weeks in general elapse before the slightest trace of respiration can be perceived in the diseased side; as the lung continues to expand, the contraction of the side gradually diminishes, until at length the lung resumes its original dimensions, and the contraction of the side disappears altogether. In some cases, however, the dilatation of the lung is never complete, and the side remains permanently contracted in consequence. Lastly, there are some cases in which recovery takes place, although the lung never expands so as to fill the space left by the evacuation of the empyema. In these cases the wound made by the operation is converted into a permanent fistula, through which the atmospheric air is allowed to enter, and the matter secreted by the walls of the cavity to escape, without producing any very considerable inconvenience to the patient's health. Several cases of this termination of the operation are recorded by Plater and Schenkinius, and by M.M. Lefacheux and Audouard.* But perhaps the most remarkable case of this kind on record is that recently published by Dr. Wendelstadt of Hersfield, who underwent the operation of paracentesis for empyema in his own person, thirteen years ago, since which time the wound has remained open, and the fluid has been drawn off twice every day, sometimes half a drachm only issuing each time, sometimes so much as three or four ounces daily. Three

* See *Empyème*, in the Dictionnaire des Sciences Médicales.

years ago, being anxious to ascertain the dimensions of the cavity which existed in the thorax, he found that it was capable of containing a quart of warm water. The diseased side is much contracted, and does not move at all in respiration, yet he can blow the flute, and walk faster than many persons who are in perfect health, and for several years he has resumed the active discharge of his professional duties.*

Various expedients have at different times been contrived for extracting the air out of the pleura, with the view of removing the pressure from the lungs' surface, and thereby facilitating their expansion. A variety of syringes have been contrived for this purpose; and recently M. Laennec has proposed to apply a piston-cupping-glass over the wound immediately after the discharge of the liquid, and to produce a vacuum in the chest, more or less quickly, continuously, and completely, according to the effects. If this suggestion were to be put in practice, care should be taken to avoid exhausting the air so far as to suck out a portion of the lung through the wound, as happened to the writer of this article, when trying the efficacy of the proposed plan on a dog. Another objection to the success of this contrivance is the difficulty of preventing the air from again rushing in through the wound the moment that the exhausting glass is removed.

After all, it appears very doubtful whether the admission of air into the pleura is really as dangerous as it is generally supposed, or whether the quantity of air which is contained within the chest affords any such serious obstacle to the expansion of the lung, that its removal may not be safely intrusted to the power of the absorbents; as the experiments of Nysten, and more recently those of Speiss, (*De vulneribus pectoris penetrantibus*.) have fully proved that air introduced into the pleura is invariably removed by absorption in the course of a few days.

In those cases where the introduction of air produces an unhealthy discharge from the wound, the practice of using injections may be had recourse to with advantage for the purpose of correcting the morbid action of the suppurating surface, and removing the putrescent qualities of the discharge. Willis relates a remarkable instance of the efficacy of injections in such cases. The fluid drawn off at the time of the operation was perfectly inodorous, and continued free from smell for the first three days; after which, whenever the wound was opened, a smell, which he describes as "odor teterrimus, cloacæ ejusvis maxime putentis fætorum superans," infected the whole chamber; but by the repeated use of injections, the horrible fetor of the discharge was entirely corrected, and the patient ultimately recovered.† M. Freteau records another case in which, shortly after the operation, the discharge assumed a dark ichorous appearance, and exhaled

a gangrenous smell; but by persisting in the use of injections for twenty days, the matter discharged from the wound assumed a healthy appearance, and lost its disagreeable odour. Willis was in the habit of using a decoction of various aromatics and stimulating herbs for this purpose. MM. Freteau, Billery, and Audouard recommend the decoction of cinchona as less irritating than that used by Willis, and equally efficacious.* A weak solution of the chlorate of lime will probably be found to act still more efficaciously as an antiseptic

(R. Townsend.)

ENDEMIC DISEASES.—*Endemic* is a word applied to those diseases which occur among the inhabitants of a particular place or country, in consequence of something local or peculiar in the air, or water, or soil, or in the food and habits of the people. Hippocrates has left a treatise, which, though containing some crude observations, is a model that has been too much neglected by medical writers. His book *De Aeribus, aquis, locis*, according to Haller, is composed in a style, and contains reasoning, worthy of its great author. If we except the Dissertation on Endemic Diseases, by Hoffmann, we have few works written expressly on the subject. Yet it is one which we might suppose would have engaged the serious attention of physicians in all ages.

The knowledge of those peculiarities in climate, soil, elevation, and site of dwelling, and especially in food, drink, and habits; as well as of the moral and physical varieties which are found to co-exist with certain forms of disease, in any part of the human family, is a branch of medical science that seems to include some of its essential principles. It is a field that well deserves to be further cultivated; and as we are now becoming better acquainted with different parts of the world by means of more accurate and intelligent observers, it is to be presumed that the data will soon be multiplied, from which, upon comparison of one country with another, many useful practical hints may be deduced, and the real causes of some hidden things in this department of our science ascertained. Of late years, indeed, much to the credit of our professional brethren both in the east and west, many excellent monographs on the medical topography of different places have appeared. An interesting article, pointing out these and other works on the subject, is to be found in the sixteenth volume of the *Edinb. Medical Journal*, in the editor's learned review of the "Medical Topography of Upper Canada, by John Douglas." But it may be truly said of endemic diseases, generally, in the words of that able reviewer, that "a complete work on the subject is one of the greatest desiderata in our professional literature."

It is needless to expatiate on those things which are obvious to every enlightened observer. As in the body, different effects result

* *Journal der Praktischen Heilkunde*, Januar, 1831.

† *De Empyemate*, p. 98.

from the dry and bracing wind of the mountain, compared with those from the moist and sluggish air of the valley; so, as regards the mind, the observation of the poet is philosophically true,—

"An iron race the mountain cliffs maintain,
Foes to the gentler manners of the plain."

GRAY.

"La terra molle e lieta e diletta
Simili a se gli abitato' produce."

TASSO.

But as the physical effects are liable to be varied by climate, elevation, temperature, winds, and the vicinity of wood and water, as well as by the quality of food and drink and the habits of life; so the moral effects (if not indeed also the physical) may be varied by the state of liberty or oppression, of sloth or activity, of comfort or wretchedness, of cleanliness or filth, of mental apathy or cultivation, in which our fellow creatures in any part of the world may happen to be placed. From all these controlling circumstances need we wonder that diseases should assume such varied appearances? or that many who are living together in the same community, and even born on the same soil, should escape some of the evils to which their less fortunate neighbours are liable? If such escape, there is less cause to wonder that entire strangers should escape also. This in fact is often the case. And when the inhabitants of any particular country or place are especially liable to some form of endemic complaint, they are found to be for the most part exempt from other serious affections. It was a proposition of Dr. James Sims, a physician of acute observation, that if a patient on the verge of pulmonary consumption could be taken into a fenny country in the height of the season, so as to contract a severe ague, there would be little doubt of the phthisical symptoms being at once arrested. The natives of a country often become inured by habit to circumstances which very soon exert a dangerous influence on strangers. The marsh miasmata of the tropics are more pernicious to strangers than to the natives. The cold winds of the northern climates most frequently affect the natives of Africa and the Indies with mortal pulmonary inflammations. It is demonstrated in countries which are inhabited by different races of men, as the negroes and Malays, the Americans and negroes, that the same circumstances do not produce the same morbid effects on both classes. It has been frequently remarked that the water of the Seine produces a diarrhoea in every one except the Parisian accustomed to the use of it. The same treatment will not be required for the same diseases, or rather for diseases called by the same name, in different places and seasons, as in mountainous and in low situations, in summer and in winter, in hot and in cold climates, in affluent stations of society and in indigent. Baglivi says that at Rome ulcers of the legs are almost incurable, while wounds in the head heal without any trouble. Cleg-horn tells us of an old proverb, that "Minorca is good for the head but bad for the shins."

In France it is remarked that ulcers of the legs are more easily cured at Montpellier, and those of the head at Paris.*

Hippocrates and Celsus both remark that obstinate ulcers of the legs frequently exist in those who are affected with enlargement of the spleen.† The cretin of the close gorges of the Vallais loses his stupidity in the dry and sharp air of the high neighbouring mountains, while the brisk mountaineer experiences less of hemorrhage and of acute disease in the heavy and cloudy air of the valleys.‡

It is an old observation that hemorrhages, acute diseases, and inflammatory affections, are more common in dry and elevated situations, especially if these are much exposed to the north wind. The contrary may be expected in opposite situations, where the "plumbeus auster" lends its aid to weaken the body and depress the spirits.

It would undoubtedly be a useful work to trace, on an enlarged scale, a connected outline of the endemic diseases in different countries, with their topography, and the food and habits of the people. But we must regret that the statements or observations, within our reach, that relate to the supposed causes of such diseases, are many of them too loose and partial for scientific generalization. With such materials, all that can be proposed at present is a very general notice of some of the leading well-attested facts belonging to the most remarkable diseases that usually come under this denomination, and for obvious reasons every thing relating to their symptoms and cure must be committed to other articles of this work.

1. *Intermittent fever*.—No observation is more general than that ague is endemic among the inhabitants of places where marshes abound, and in seasons, as the spring and autumn, when the effluvia arising from them are more active, and the body perhaps more liable to be affected by their peculiar poison. There are few marshy countries, in temperate and tropical climates, in which intermittent fever is not known. The connexion, therefore, between them does not depend on a *limited*, but a comprehensive induction of facts: the truth is abundantly confirmed. Ague, indeed, sometimes appears where the influence of marsh effluvia cannot be traced; and the term *malaria* has been brought into modern use to denote a morbid atmosphere, arising from the soil, capable of producing intermittent fever, in which marsh *miasmata*, properly so called, are supposed not to constitute an essential part. Many facts would seem to countenance this opinion, as well as that which assigns to malaria the production of continued fever under certain circumstances. In the metropolis we have known persons attacked with ague, mostly however of an irregular type, by working in damp cellars. In temperate climates, under ordinary circumstances, the milder forms of the disease appear, and these in the spring, as the quotidian and

* See Dict. des Sc. Méd. art. *Endémique*.

† Cleg-horn, op. cit. p. 71.

‡ Virey.

tertian. The quartan, more obstinate and protracted, usually appears in autumn. In Sydenham's time, and even in that of Fothergill, the quotidian of spring became continued fever in summer; while the simple continued fever of summer often changed to a malignant type in autumn. These were simple observations at a time when systematic arrangements had not put physicians in trammels. But now, lest we should be guilty of medical heresy, we must not insinuate that ague can change into continued fever, and non-contagious fever into contagious typhus, either in an individual case or in the course of the year!

It has been commonly observed that the spleen suffers more in cases of protracted intermittents in temperate climates, and the liver in tropical. Nevertheless, Dr. Jackson tells us of enlarged spleen after such fevers in the West Indies: Cleghorn noticed the same in Minorca; and we have the testimony of W. Twining, that this organ is often found diseased from this cause, in Bengal and all the low districts of Hindostan.*

When tropical heat is added to the influence of marsh effluvia, then we have the various shades of intermittent, remittent, and even continued fever, passing sometimes into each other by almost imperceptible gradations, and complicated more or less with bilious symptoms. When intemperate seasons, deficient or unwholesome food, and animal filth, are superadded to the causes above mentioned, and acting upon a condensed population, the highest grades of pestilential fever are often exhibited, as the plague of Egypt and the Levant, the pestilential fever of Spain, and the yellow fever of America and the West Indies.

When marshy land is brought to a very dry state in summer, after long continued drought, ague is often but little known in the vicinity; but the first heavy shower after the drought will sometimes give rise to it. And on the contrary, in a wet season, while much water is lying upon the marshes, the disease is rare; but in proportion as they become dried to a certain point, the *miasmata* are found to be active, according to the degree of heat, the season of the year, and the state of the population. A certain quantity of moisture, therefore, seems to be necessary upon the marsh, in order that the *miasmata* may be disengaged; and of vapour in the atmosphere to convey them to a distance; while a superabundance either prevents their evolution, or entirely absorbs them.

Notwithstanding that the notion has been ridiculed by a few, there can be little doubt that currents of air will sometimes waft the effluvia to a great distance, so as to produce intermittent fever in places otherwise healthy; and some facts would seem to show that hills of a certain elevation in the vicinity of marshy grounds have a sort of attraction for the *miasmata*, and are almost as unwholesome as the plains.† But it is upon a different principle

that hilly grounds, in some cases, become more unhealthy than the plains. The British army in 1809 found that the hilly sides of the ravines in Portugal, after heat and rain, exposed the soldiers to a most destructive remittent, while the overflowed swamps below were more than usually free from disease: "and such," says Irvine, "is frequently the case on the lofty ridges of Sicily, when their fiumari, or water-courses, which are ordinarily dry, and used for roads in the summer months, are filled and inundated with sudden torrents of rain. For here the malaria changes its station, and quits the overflowed low lands for the heights of the primitive hills.**"

Plantations of trees have been known to intercept marsh miasmata, and thus to prevent their injurious effects upon the inhabitants at a short distance; and for the same reason it is found that the site of a dwelling should not be too near such plantations. "It is wonderful," says Dr. Ferguson, (loc. cit.) "to see how near to leeward of the most pestiferous marshes, in the territory of Guiana particularly, where these trees abound, the settlers will venture with impunity to place their habitations, provided they have this security; though every one is fully aware that it would be almost certain death for an European to sleep, or even to remain after night-fall, under the shade of the lofty trees that cover the marsh, at so short a distance.†"

There is something curious and not easily explained in the circumscribed locality of intermittent fever in certain places. Perhaps, if the prevalence of winds and the situation of such places as to exposure and wood and water, &c. were taken into account, the difficulty might be in part removed. A late writer on malaria states that on the high Dover road, in Kent, not far from Rochester, some of the people living on one side of the road were attacked with ague, while on the other side all escaped.

It is amply proved that marsh effluvia exert far more pernicious influence upon the body during the state of sleep, or even when it is exposed to them in the night air without sleep. It has also been observed, in illustration of the *ague-giving* qualities of the east-wind, that some time, even days or weeks, after an exposure to marsh miasmata has taken place without producing any perceptible bad effect,

1821; Dr. Ferguson on Marsh Poison. Dr. Robertson fully confirms the observation of Dr. Ferguson relative to the exposure of the inhabitants of high situations in the vicinity of marshy grounds to the effects of the *miasmata*. (Med. Repos. vol. i. p. 367.) He knew people to be severely affected by this cause, who had not been for some time without the walls of the castle of Santa Barbara, at Alicante, 800 feet above the sea-shore; while at the same time, persons living on a level with the sea, and exposed to all the sources of marsh miasma, escaped every attack of fever. He considers that the high grounds present an impediment to the free dispersion of the exhalations through the atmosphere.

* Good's Study of Medicine, vol. ii. p. 166.

† Med. Chir. Rev., Dec. 1821.

* Calcutta Medical Trans. vol. iii. p. 354.

† Medico-Chir. Review, vol. ii. p. 591, Dec.

the casual blowing of the east wind has at once fixed an attack of ague. Sea-water flowing over marshy ground, *cateris paribus*, seems to give rise to more pernicious effluvia than fresh water. The bogs or peat-mosses of Scotland and Ireland, on the other hand, do not appear to generate ague.

Dr. Clark, in his late work "On the Influence of Climate," states, that with regard to Rome, at the present time, "a certain period of residence in the malaria site is necessary, in general, to prepare the body for its attack; and that there is no reason for the fear commonly entertained of a sudden attack of malaria from simply passing quickly through a malaria district." "The German, French, and English artists were more frequently attacked with fever the second or third years of their residence at Rome than the first." But the situation of this city will not bear an exact comparison with that of a pure marshy district.

Seamen, who after a long voyage venture to land on a marshy shore in the height of the season, too often find that if they remain a single night on land, they are attacked by the endemic fever almost immediately. Hence it has often happened that vessels coming to a maritime city, on the eve of a pestilential visitation, although with clean bills of health, have been among the first to show signs of disease in some of the crew; and the fact has been eagerly laid hold of to countenance the suspicion that contagion from the vessel gave rise to the distemper; for it need not be told that mariners who have been long at sea are very susceptible of morbid impressions from a vitiated atmosphere on first coming to land in a sickly season.

As a common rule, regular sufficient diet affords some protection against the influence of malaria; and fatigue, low living, debauch, night-watching, and irregularity of every kind, favour its attack. In temperate climates, where these miasmata abound, the practice of over-excitement with stimuli will do less harm than in hot countries.

2. *Bronchocele*.—From the line in Juvenal, "Quis tumidum guttur miratur in Alpihus?" it would seem that the swelled throat was so common a complaint in the Alps in his time, as not to excite any wonder. It is still found in the valleys of the Alps, and in some other mountainous countries, as the Pyrenees, the province of Behar in India, in Derbyshire, &c. It has been observed also in some mountainous parts of Java and Sumatra; but it is rare in Scotland; and Dr. Reeve states that it is very common in Norfolk. Mungo Park observed the bronchocele in different parts of Bambara, in Africa, along the course of the river Niger. Females are far more liable to it than males. The opinion that snow-water is the cause of this complaint appears to be quite unfounded; nor can we ascribe it to the use of water impregnated with calcareous earth. Yet it is probable that air, water, and diet, each contribute something towards the cause. Sir S. Raffles tells us that there is a village, near the

foot of the Teng'gar mountains in Java, where every family is afflicted by this malady; while in another village, situated at a greater elevation, and through which the stream descends that serves for the use of both, there exists no such deformity.

In the province of Behar in India, there is a district called Tirhoot,* in which bronchocele is common among the natives: "and a singular circumstance regarding it is, that on a small river of the district it is not uncommon to see a village on each bank, and quite contiguous, the one with scarcely an individual exempt from the complaint, while in the other the inhabitants are perfectly free from it."

Dr. Johnson cogently remarks,† "that we observe goitre more abundant in some than in other parts of Switzerland, though the diet is the same. In the valley of the Rhone we see hardly any thing else than cretins and goitres; while, in the valley of Chamouny, separated only by the Col de Balme, we see very few of either disease. We trace bronchocele along the whole course of the Rhine, from Schaffhausen to Cologne; it gradually decreases as we descend the Rhine; and among those who inhabit the banks and drink the waters of the upper or turbid Rhone (in the Vallais) there are twenty goitres and cretins for one that can be seen on the banks of the lower or filtered Rhone." Taken in connexion with the Rhine, it forms (in his opinion) a strong ground of presumption in favour of the *goitri-factive* influence of Alpine waters. Dr. Johnson, however, does not ascribe all the effect to the waters; and he adds, that "English children (who live as well as people in England) cannot be kept long at Geneva without having enlargements of the thyroid gland." He concludes, therefore, that the cause cannot be traced to sour bread, as Dr. Brug imagined, or to any particular article of diet, except water.‡

Notwithstanding the foregoing testimonies, the observation of Dr. Mason Good is very important, that at Matlock in Derbyshire he found "a large number of the poor affected with bronchocele, while the rich escaped;" and by far the greater part were exposed to all the ordinary evils of poverty.§

Bronchocele has been observed to prevail most in situations where humidity is joined

* Calcutta Transactions, 1829, and Edinb. Med. and Surg. Journal, No. 106.

† Med. Chir. Rev. vol. vi. p. 422.

‡ In the work of this able writer and philosophic observer, lately published, entitled, "Tour of Health, &c." he says, "Dr. Bally, a native of a goitrous district in Switzerland, states the following very important fact. Bronchocele appears to me to be produced by certain waters which issue from the hollows of rocks, trickle along the cliffs of mountains, or spring from the bowels of the earth. That this is the case I may instance some families in my own country, Département du Lemau, au Hameau de Thuet, the use of whose waters will in eight or ten days produce or augment goitrous swellings. Such of the inhabitants of the above village as avoid those waters are free from goitre and cretinism."

§ See Study of Med. vol. v. p. 309.

with excessive heat; and it is found to increase in spring, and to diminish in autumn. Upon the whole, a more ample induction is required before the true causes of the complaint can be determined: the probability seems to be that these are not uniform, or, at least, that they are liable to be much varied; and that a peculiar combination of air, food, and water has much to do in causing the complaint.

3. *Cretinism*.—This singular compound of mental and physical deformity is found in situations, as in the Alps and Pyrenees, not unlike those which give rise to bronchocele, with which it is sometimes but not always complicated. It was first described by Felix Plater in 1635, who saw it in Carinthia and the Vallais about the time the rickets, with which it seems to be connected, was observed in England by Glisson. Cretinism was observed by Sir George Staunton in a mountainous part of Chinese Tartary.* A race of cretins has also been noticed by Ramond in the south of France, where they are widely extended, under the name of Cagotts.

The large deformed head; the low stature, the sickly complexion, the vacant and unmeaning countenance, the coarse and prominent lips and eye-lids, the wrinkled and pendulous skin, the loose and flabby muscles, are the physical characters belonging to the cretin, which correspond with an almost obscured or feebly glimmering intellect to form one of the most degraded varieties of our species.

According to Saussure, the valleys where cretinism is most frequent are surrounded by very high mountains, sheltered from the currents of air, and exposed to the direct, and still more to the reflected rays of the sun. The effluvia from the marshes are very strong, and the air is humid, close, hot, and oppressive. Dr. Reeve, who has given a very interesting account of this disease in the fifth volume of the *Edinb. Med. Journal*, says, that "all the cretins were in adjoining houses, built up under ledges of the rocks, and all of them very filthy, very close, very hot, and miserable habitations. In villages situated higher up the mountains no cretins are to be seen; and the mother of one of the children told me, of her own accord, that her child was quite a different being when he was up the mountain for a few days."† It is gratifying to think that the number of cretins is diminishing. It is well observed by Dr. Reeve, that "there is no fact in the natural

history of man that affords an argument so direct and impressive in proof of the influence of physical causes on the mind, as cretinism. It may be prevented by removing children from the confined and dirty places where it prevails, and nursing and educating them in the higher parts of the mountains." He further states, that the disease is looked upon as belonging to indigence and poverty; for, in every place where he saw cretins, many well-looking persons of both sexes resided, and these were, *without exception*, persons of a higher class in society, who lived in better houses, and could supply both their moral and physical necessities.

The production of cretinism by the bad quality of the air and food, the neglect of moral education, and other evils attendant on poverty, is sufficiently proved by the advantages that have attended the use of those prophylactic rules laid down by Foderé, in his interesting and classical work on bronchocele and cretinism. And the diminution of the number of cretins is ascribed to the draining of the fens, the more healthy situation of the huts, the clearing of the woods, &c., and, lastly, to the progress which has been lately made in education among them.*

4. *Plica, trichoma, plaited hair*.—No mention is made of this disease either by the ancients or Arabians. Whether it first appeared in Poland, in the thirteenth or the sixteenth century, is doubted by authors. Pistorius refers to the first period, Thuanus to the second. Though plica is more frequently observed in Poland and Lithuania (and less so than formerly) than in other countries, yet it is seen occasionally in Hungary, Transylvania, Prussia, Russia, and Great Tartary, as well as in Switzerland, Belgium, and some parts of France. It is, however, considered to be the endemic of Poland. Many marvellous stories are current in relation to this disease, not only about the causes and contagious nature of it, but the danger of attempting a cure. Whatever the disease may have been formerly, as to its violence and general tendency to supersede other morbid affections, in persons constitutionally or hereditarily liable to it, Alibert, De la Fontaines, Baron Larrey, and others have lately thrown much light upon the complaint, and have proved that inattention to cleanliness, and the peculiar habits of the Poles, have much to do with the occasional causes. Dr. Louis Kerckhoff† does not doubt that filth is now the cause of it, united to the constant habit of the lower classes in Poland of wearing long hair, which, in the hottest weather, none of them ever clean or comb, and keeping the head always covered either with a thick woollen bonnet or a leathern cap. To prove that it was not contagious, he inoculated himself and two children from the fluid filling the bulbs of the hair, which he had taken from a boy labouring

* See Good's Study of Med. vol. v. p. 334.

† A curious observation is made by Dr. Akerman on this subject. (See Dr. Thomas' Practice, p. 605.) "Those who inhabit the deepest and most reclusé valleys are reduced to the lowest state of imbecility and idiotism; in those who are somewhat more elevated, the mental powers are not so completely obtunded; and others, still more elevated, and of course less exposed to exhalations, will probably be deformed merely with wens or swellings about the joints, and other symptoms of rachitis. Those who are nearer to the summits are perfectly exempt from all these appearances." These facts show a very singular correspondence between degrees of elevation in those mountainous districts, and a graduated scale of disease lessening towards the summits.

* See Medical and Physical Journal, vol. v. p. 176.

† See Med. Trans. of the Col. of Phys. Lond. vol. vi.

under the complaint, without any effect. He and the French surgeons had no difficulty in curing the disease, in several instances, by cutting off the matted and filthy hair, and directing the head to be suitably washed. It must, however, be acknowledged that in some families there seems to be such a predisposition to the complaint that slight causes are sufficient to induce it, and in some cases even strong mental emotions have given rise to very sudden attacks of it.* Dr. Vicat† assigns three causes for this complaint. The first is the nature of the Polish air; the second unwholesome water, for the common people usually drink that which is nearest at hand, taken from rivers, lakes, and even stagnant pools; the third cause is the gross inattention of the poor to cleanliness, for the better class are far less liable to it than those of inferior stations; the inhabitants of large towns than those of small villages; and the free peasants than those in a state of vassalage. Dr. Kerckhoffs confirms the fact that the rich are generally exempt from plica, and that it is seldom seen but among the poor, “who wallow in filth and misery”—(qui croupissent dans la misère.)

5. *The Guinea-worm*.—Plutarch‡ states that those who live near the Red Sea are liable to a disease in which small worms, called *dracontia*, are found in various parts of the body. Kemper observed the disease in the island of Ormuz, in the Persian Gulph, and also in Tartary. According to Welsch, it is known to prevail among the negroes in all the marshy parts of Africa. The worm is a native of both Indies. Dr. Chisholm, who has given the fullest and best account of the dracunculus that we have seen,§ says that the complaint is not confined to the natives of Africa in the West Indies, and that it is an endemic, and, during a certain portion of the year, an epidemic disease, in the island of Grenada, where he practised. In one estate of this island all the field-negroes, about three hundred, who drank of a particular well, had the disease every year, in the months of November, December, January, and February, for several years, (or from the year 1787, when the well was dug, till 1794, when Dr. Chisholm left Grenada;) and from March to November not an instance of the disease occurred among them. In another plantation the same thing was observed, and after cisterns were made to hold rain water for common drink, and the wells were filled up, the disease entirely disappeared. The domestic negroes and whites who drank *rain* water, while the *well* water was in use, generally escaped. Three infants, from five to seven months' old, to whom their mothers had incautiously given the water of the well, had each a worm in one of their legs; and a domestic negro boy, who in the year 1793 drank of the *well*-water, had several Guinea-worms the same year, and *only that year*. In a third plantation similar facts

were noticed; none of the whites on the estate had the disease except one, who inconsiderately or ignorantly drank of the well-water.

Bruce and Mungo Park give a similar testimony respecting the effects of particular wells in Africa; and Dr. Chisholm concludes that “in all countries in which the dracunculus is endemic, the prevailing belief of the people is that it proceeds from drinking water which contains the ova or the embryo of the animal.”

It is a singular fact that the disease is observed to prevail at Bombay and along that part of the coast of India about the same time of the year when it prevails in the West Indies, viz. in the months of December, January, and February. It also appears in many other districts in the Carnatic and Madura, to within the distance of one or two days' journey from the sea-coast. A learned missionary, named Dubois, in a letter to Dr. Anderson, the physician general, states that he has often seen villages in which more than half the inhabitants were affected by it at the same time. The inhabitants of a village who drink water from one well are attacked by the disease, while the inhabitants at the distance of only half a mile who drink water from another well are not affected by it. Besides, the inhabitants living on the shore of the Cavary and other rivers, who constantly drink their limpid waters, are never visited by it; while those who live at the distance of one mile on both sides, and are obliged to drink the saltish water of wells, are all, or the most part, *yearly* exposed to it.

Dr. Smyttam* confirms the observations of Dr. Chisholm and others that “an argillaceous (*and tuffy*) soil, with a considerable impregnation of salt, or percolated by sea-water, is what the Guinea-worm affects.” And another fact seems to be pretty well ascertained, both in the East and West Indies, that the worm not only insinuates itself into the body *through the skin*, but that its ova may be conveyed into the system through the stomach, and deposited in the cellular membrane under the skin, where it attains its growth, and at length produces that local irritation which leads to its expulsion.

The fact that those who are affected with the dracunculus rarely suffer from any other disease at the same time, with a few other reasons which appear entitled to little weight, has led some persons, and lately Dr. Milne of Bombay,† to maintain the position that the substance which is observed in this disease “is not a worm, but a lymphatic vessel.” We cannot take further notice of this opinion, nor is it necessary to advert to the circumstances which led Sir James Macgrigor to conclude that the dracunculus was contagious, as the facts have been explained by Dr. Chisholm on a far more reasonable hypothesis.

The Guinea-worm has been rarely seen in its native state *out of the body*. Nevertheless, the observations of Dr. Helenus Scott of Bom-

† Edinb. Med. and Surg. Journal, No. 106.

bay,* and recently those of Dr. Robert Grant,† set the question of its independent existence at rest.

6. *Nostalgia*.—The concurrence of depressing symptoms which sometimes arise in persons who are absent from their native country, when they are seized with a longing desire of returning to their home and friends and the scenes of their youth, constitutes the disease called nostalgia. Some have considered it peculiar to the natives of Switzerland, because it was often observed in the Swiss soldiers when on foreign service. But, alas! too many instances of this affection occur in the natives of other countries, and evince that it has its source in the very frame and constitution of human nature in every part of the world. Though it might appear that the inhabitants of mountainous countries were more liable to nostalgia than others, yet many instances have occurred in which a removal from the plain to the mountain has produced this melancholy. It would seem as if no country were too wild and savage, if but the simplest means of supporting human life were at hand, not to attach the natives to it. Our affections, like the tendrils of the vine, adhere to the objects that are first presented to them, whether animate or inanimate, with so firm an embrace that nothing but violence can break the connexion.

Every one accustomed to the variety and beauty of mountain scenery, and capable of feeling intensely the delights of rural manners, can conceive without difficulty the anguish and shock to the physical powers, which is often sustained by those who are thus ardently devoted to their friends and native country, when they have been rudely separated from them.‡ The Laplander feels the most enervating and listless despondency, when absent from his snowy mountains and frozen lakes. The North-American Indian sighs amidst the festivities and comforts of polished life for the earthy couch in his native wilds, and the free range of his interminable forests. And the poor negro, even if cruel bondage were not his portion, might be expected to utter bitter complaints for the loss of family endearments and of the noontide repose in the sultry retreats of African luxuriance. Many of the ill-fated Africans, it is well known, perish from *suicide* and *dirt-eating* in those polluted and polluting islands, where we cannot say that

“No fiends torment nor Christians thirst for gold.”

Even the hardy and almost unyielding nature of the British seaman, when he has just set foot on his native land after a long voyage, and been pressed against his will to leave once more the objects dearest to him in life, has often been subdued by this powerful influence so com-

pletely as to be quite disqualified for the duties to which he was called. Within the last forty years, perhaps no country in Europe has afforded so many instances of the overwhelming influence of the disease in question as France, notwithstanding the natural buoyancy of spirit and thirst after military glory for which that nation is distinguished. There was scarcely an encampment during the war in which the skill of the medical attendants was not called forth, assiduously and painfully, to counteract the pernicious effects of nostalgia,—pernicious, and, indeed, often fatal in a high degree, when any other debilitating or depressing powers were applied at the same time, and acting together with this epidemic melancholy upon the young soldier. It was then observed that a slight wound, dysentery, fever, extra fatigue, or a disastrous engagement, hurried multitudes into a state of mortal depression.*

7. *Tarantismus*.—A disease was formerly supposed to be endemic in Apulia, and only in that part of Naples, which was so called from the spider named *aranea tarantula*, whose bite was said to be the cause of it. The peculiarity of the disease mainly consisted in the uncontrollable propensity of the sufferer to dance in the most violent manner at the sound of certain music—some affected by one sort and some by another—till copious perspiration and excessive fatigue put an end to the disease, and thus destroyed the effects of the poison. This was the common opinion, and men of science received it as agreeing with matter of fact. Tarantismus affords one of those humiliating lessons which may too frequently be drawn from medical records, on the difficulty of ascertaining facts, and the prevalence of unfounded opinions, even among distinguished physicians. Kircher, Sir Thomas Browne, Baglivi, Boyle, and Mead have not hesitated to give credit and countenance to the statements relative to the wonderful effects both of the bite of the tarantula spider upon the body, and of the music as a remedy. Yet it would appear that they were all misled by a popular error. The treatise on the tarantula of a physician so eminent as Baglivi, who was himself an Apulian, tended to confirm the delusion.

On the contrary side of the question we have the strong testimony of Dr. Cornelio, a Neapolitan physician, so far back as 1672, of Dr. Serao, an Italian, and of Dr. Cirillo, professor of natural history in the university of Naples, so lately as 1770, besides that of many others since their time.† Cornelio says that “all those that think themselves bitten by tarantulas, except such as for evil ends feign themselves to be so, are mostly young wanton girls, who persuade themselves they have been stung by a tarantula, according to vulgar prejudice, in consequence of having fallen by some particular indisposition into this melancholy madness.” Dr. Serao has written an

* See *Medico-Chir. Review*, vol. iv. 1823.

† *Edinb. Med. and Surg. Journal*, No. 106.

‡ The celebrated Swiss air called *Ranz des Vaches*, imitating the full rebounding echo of the Alpine herd amongst the mountains, might well awaken mournful recollections in the bosom of the absent soldier, so as to require that the playing of it should be prohibited under a severe penalty.

* See *Percy and Laurent, Dict. de Sc. Méd. art. Nostalgie*.

† See *Phil. Trans.* for 1672 and 1770.

ingenious book, in which he has effectually exploded this opinion as a popular error. Dr. Cirillo asserts that, "having had an opportunity of examining the effects of this animal in the province of Taranto, where it is found in great abundance, he finds that the surprising cure of the bite of it by music has not the least truth in it. In Sicily, where the summer is still warmer than in any part of Naples, and in Tunis also, where this spider is found, the tarantula is never dangerous, and music is never employed for the cure of the pretended tarantism."^{*}

Dr. Laurent, who lived in the kingdom of Naples for a long time as chief surgeon to the French army, says that the bite of the tarantula does really cause a slight inflammation, but that tarantism, as described by authors, no longer exists. He has often seen, at Naples, ten or a dozen young girls running about the streets, each having a small tambour, and performing with a kind of violent effort, accompanied by the most wanton gestures, the dance they call tarantella, a national dance from time immemorial known in that country. Hence, Merat thinks it probable that tarantismus, *the disease*, is nothing but tarantella, *the dance*, adorned with some fables. Nollet, an eminent physician, was satisfied, when in Italy, that the vulgar notion was unfounded; that, even in Apulia, sensible people gave no credit to it; and that it was only some of the very lowest class, who, pretending that they were bitten, appeared to be cured by dancing and music, in order that they might gain a subsistence by this kind of imposture. We are assured that the opinion of all the physicians of the country is that the bite is harmless, if not aggravated by improper applications; and that they consider the pretended tarantism arising from it as visionary. Baglivi himself admits that "this spider is only venomous in the *dog-days*, and in very hot situations, for, *at other times, and in the mountains, and in other countries, it is not so.*" This is a remarkable concession.

The fact is, that the inhabitants of Apulia, breathing a hot and dry air, are liable to inflammations of the head and chest, and to spasmodic affections; and sufficient grounds appear for considering the aggregate of symptoms, called tarantismus, as a nervous complaint, incident to a people naturally choleric, ardent, impatient, liable to insanity, fond of a dance of which violent gestures constitute a peculiarity, and easily affected by music.†

Besides the diseases above noticed, some others are classed with endemics, as beriberi, attributed to the alternation of extreme heat in the day with cold and damp in the night; ophthalmia, in Egypt, to solar heat and an adust air imbued with impalpable sand; elephantiasis, in the same country, to corrupt water and the use of salt indigestible food amongst the poor, added to filth in houses and persons; pellagra, in Milan, and a species of lepra, in Asturia, to bad food and sordid

habits also; frambæsia, or yaws, in Africa, and among the negroes in the West Indies; tetanus and trismus in tropical climates, east and west; the Barbadoes, or Cochin leg, &c., to causes not well ascertained. Respecting each of these some interesting facts might be stated; but we have only room for a few general observations.

In the first place, we may remark that abject poverty is the soil in which most endemic diseases spring up in every country. Upon the poor, ill-fed, harassed population, living in closeness and filth, these diseases commonly fall, while those who live well and are but little exposed to the injurious qualities of air, soil, and water, are in great measure exempt. Secondly, if we may form any just idea of the causes of physical evils in general, from a consideration of the means which have been found useful in preventing them, then it is clear that, although some complex appearances and seemingly contradictory facts enter into the catalogue of assigned causes of many endemic diseases, so far as they appear to depend on air, soil, food, and drink; yet, on the other hand, proper attention to these things is found, in almost every instance, to be effectual in suspending and finally removing the maladies in question. By draining marshes and cultivating lands, by providing plain sufficient food and wholesome water, with airy dwellings for the poor, it cannot be doubted that a host of physical evils would be avoided. Thirdly, had we time to pursue this subject further, there is wide scope for reflection on the duties which devolve upon the rich in every country to relieve the necessary wants and sufferings of their poor neighbours; on the provision which is made in the nature of things, by a bountiful Creator, for the relief of human misery, in every climate and in all situations of life, if man himself, or at least those who are in power, would but apply the means—if luxury would make a small sacrifice of self-indulgence to the public good; and, lastly, on the physical blessings that would result from this wise paternal care, not only comforting and rejoicing the poor objects themselves, but enriching their benefactors, causing the face of nature to smile around them, and giving them the never-failing reward of sound policy and of Christian benevolence.

(T. Hancock.)

ENEMA. See INJECTION.

ENTERITIS. This term has been long used in medicine to express an inflammatory state of the intestines, but it is only within our own time that pathologists have attached any definite meaning to the expression. In the older books we read of *gastritis*, *peritonitis*, and *enteritis*, of which latter Cullen describes two species, the phlegmonous and erythematic; and it is remarkable that by a species of consent among medical men the term has been chiefly used to express the first of these species, or the acute inflammation of most if not all the coats of the intestine. But modern re-

* See Edinb. Med. and Phys. Dict. art. *Aranea*.

† Dict. des Sciences Méd. art. *Tarantisme*.

searches have greatly extended our views of enteritis, although the true pathology of the intestine is not yet sufficiently recognised by most practitioners.

Enteritis is now known as a disease perhaps the most protean of any of the affections of the body; occurring with every variety of intensity, from a slight and circumscribed vascularity to the most extensive disorganization; simulating by its numerous sympathetic irritations many of the diseases of the nervous, respiratory, circulating and genito-urinary systems; accompanied by the most violent symptoms of irritation, or only pointed out by a profound adynamia; or, lastly, advancing with perfect latency to incurable disorganization. A formidable disease in its idiopathic form, its supervention in the course of other affections is a matter of daily occurrence, and in one particularly, (fever,) a common cause of its fatal termination. We shall dwell on this part of the subject hereafter, and endeavour to show that the enteritis of typhous fever is more a consequence than a cause of the disease, but still not the less important in its prognosis and treatment. Compared with other affections, both acute and chronic, the frequency of intestinal disease must strike every observer. Andral, who, from his vast experience, and the fact of his having no theory to defend, is the best authority on this subject, declares that in the great majority of acute diseases of other parts, a derangement either in the functions or structure of the intestinal canal will occur; and that in chronic diseases, whatever be their nature, it is extremely rare that the digestive tube escapes alteration. These complications of course form part of our subject, but here we shall merely remark that it is difficult to estimate the benefit which Broussais has conferred on medicine by calling the attention of pathologists to the frequency and importance of irritations of the digestive system; and if, in the ardour of discovery, this great physician has in one instance passed the bounds of strict induction, the error is more than atoned for by the extensive good of which he is the undisputed author.

We shall here treat of the different inflammatory affections of the intestinal canal, from the pyloric end of the duodenum to the rectum, reserving the consideration of gastritis and peritonitis for separate articles.

We recognize inflammatory affections of the digestive tube by the alterations of function, the local phenomena, and the sympathetic irritations which occur. The general symptoms may be enumerated as follows: indigestion, anorexia, vomiting, thirst, jaundice, tympanitis, constipation, alteration of the fecal discharges in quality or quantity; pain, tenderness on pressure, contraction of the features, morbid state of the tongue, dryness of the skin, and conjunctiva; suppression of urine, sighing, stupor, delirium, headach, prostration, accelerated and thoracic respiration, fever.

We shall find that the greatest variety in the combinations of these symptoms may occur, principally arising from the following circumstances:—the intensity and extent of the inflam-

mation;—the situation of the disease, both as to the different parts and tissues of the tube;—the complications with other diseases;—the different degree of excitability of the nervous system in different individuals. Thus, when the inflammation is extensive and severe, occupying both the stomach and intestines, we may have the worst forms of bilious or gastric fevers; when it occupies the duodenum, jaundice is a common symptom, and the disease may occur with or without fever: in the small intestine a slight inflammation is often nearly latent, or only pointed out by a little swelling or pain, while in the cæcum or colon the disease produces all the varieties of diarrhoea and dysentery. When the upper portion of the tube is engaged, constipation is a common symptom; when the lower, the reverse takes place. If the mucous membrane alone is engaged, pain and costiveness are often absent; but when all the coats are in a state of acute irritation, we may find the most violent symptoms of peritonitis and ileus, with contractions, intus-susceptions, &c. The complication of the disease with other affections also produces great varieties. Thus when it occurs in the advanced stages of phthisis, diarrhoea is often the only symptom; or when complicated with erysipelas or pneumonia, its most prominent indication is an extraordinary prostration. The different degrees of excitability of the nervous system cause the greatest irregularity of symptoms: in the child, acute enteritis is commonly mistaken for inflammation of the brain; in the adult a circumscribed irritation will in one case be accompanied by violent delirium, while in another, more severe, this symptom shall be completely absent.

We have already spoken of the great frequency of abdominal irritations occurring alone, or in combination with other affections. This knowledge is the discovery of our own time, and may be looked on as the greatest improvement in modern pathology. The humoral school could see in most digestive derangements nothing but the accumulation of sordes; and hence the emetic and purgative practice, in cases where a decided inflammation existed in some part of the tube. They never thought of treating inflammatory diseases of the abdomen as such, unless when they occurred in the highest degree of intensity, involving all the coats of the intestine; and of the nature and symptoms of irritations affecting the mucous system they were almost wholly ignorant. The followers of Brown, on the other hand, saw in these affections only debility, because most of them are accompanied by prostration of strength, functional injury, a weak pulse, and in some cases by completely typhoid symptoms. Ignorant of the fundamental law of pathology, that local excitation or inflammation may coincide with a diminution of the general vital force, they prescribed stimulants, which only increased the debility by exasperating its cause. The progress of medicine has shewn, that to various modes and shades of irritation of the gastro-intestinal surface, a great number of affections, the nature of which was previously obscure, are

to be referred. We now know that many cases of what has been called idiopathic fever are of this nature, and that it is a common source of dyspepsia, hypochondriasis, jaundice, hepatic obstructions, and tympanitis; that diarrhoea and dysentery constantly arise from it; and that in very many cases ileus, constipation, infantile remittent, tabes mesenterica, melæna, and hemorrhage from the bowels, are results of this morbid state. To this cause also may be traced many of the irritations of other systems: it may produce hysteria, epilepsy, tetanus, mania, cough and accelerated breathing, palpitation, suppression of urine, dropsy, rheumatism, and disease of the skin.

We shall endeavour to study the history and symptoms of enteritis separately from those of gastritis, as far as this is possible; for in many cases the coincidence of the two affections prevents this analysis. We shall examine first the *acute and chronic enteritis of the infant*; and, secondly, these affections in the adult. Enteritis may be an intra-uterine disease; and it appears probable that many of those infants who continue in a state of debility and marasmus from birth, have really been born with this affection. In some infants who have died but a few days after birth, unequivocal marks of chronic inflammation of the intestine have been found; and in others who have lived but two days, the various appearances of more acute irritation have been observed. These facts render it probable that the delicacy of infants may often be owing to this cause, and should render practitioners much more cautious in the use of the tonic, stimulant, and purgative treatment.

During the period of lactation, infants are extremely subject to inflammation of the mucous membrane of the intestines, a circumstance attributable to the high degree of susceptibility which the tube is endowed with, and the great activity of the digestive function; and in most countries also, the irregularities of diet, and the frequent use of stimulants and purgatives powerfully aid in producing this result.

Enteritis may occur in the infant under two principal forms: in the first there is absence of fever, and frequently of the other sympathetic irritations, the symptoms being merely local: in the second we have the local symptoms, but with fever and signs of irritation in the nervous and respiratory systems. The first form is that to which the youngest infants are most subject, the second being more liable to occur as the child advances in age. As in the adult, the symptoms vary with the portion of the tube affected, and in the youngest children they are most commonly those of gastritis and enteritis. Vomiting, diarrhoea, tympanitic swelling and pain on pressure are the most common symptoms of this disease. The tongue is most generally dry, furred, and red at the tip, and the skin dry; and when diarrhoea exists, an erythematous redness round the anus has been observed. Fever may or may not be present, and it often happens that the abdomen feels preternaturally hot. Towards the fatal termination of the disease the skin becomes cold, wrinkled, rough, and of a dirty appearance; the emaciation

is extreme, and the muscles are soft and flabby. The character of the face is remarkable; the hollow cheeks, corrugated forehead, and retracted mouth giving to the child a melancholy and singular expression of age and suffering.

Dr. Abercrombie describes this disease in children of from six to eight months old, and states that in its early stages it is difficult to distinguish it from the ordinary bowel complaints of children at the period of dentition. He relies principally on the occurrence of fever, but we have seen that in the very young child this is insufficient, the symptoms being merely local. The following is his account of the symptoms:—"The infant is usually hot and restless in the early stages, with thirst; and the tongue is dry, or covered with a brownish crust: there is in general a good deal of screaming and fretfulness, disturbed sleep, frequently vomiting, and in many instances pressure on the abdomen appears to give uneasiness. The bowels are loose, but this is not in every case a prominent symptom, for even in the advanced stages the bowels may not be moved above three or four times in the twenty-four hours, while the disease is advancing rapidly to a fatal termination. In other cases, however, this symptom is more urgent, the evacuations being preceded by much restlessness and appearance of pain, and the matters evacuated are sometimes discharged with a remarkable degree of force, so as to be propelled to a considerable distance. The evacuations vary considerably in appearance, and I have never been able to satisfy myself that any reliance is to be placed upon them in ascertaining the disease. They sometimes consist chiefly of a reddish brown mucus, sometimes of a pale clay-coloured matter, and sometimes of a dark watery fluid; but in many cases they shew little deviation from the healthy state, while in others their appearance is evidently disguised or modified by articles of nourishment, which pass through nearly unchanged. The disease often goes on for some time without exciting alarm or being distinguished from an ordinary diarrhoea, until attention is suddenly directed to it by the occurrence of constitutional symptoms. These consist in some cases of a great degree of febrile oppression, with dry crusted tongue, thirst, and vomiting; in others, of a very sudden and rapid exhaustion of the vital powers, which is unexpected, and not accounted for by the frequency of the evacuations; and sometimes the first appearance of unfavourable symptoms consists in the occurrence of coma, with a peculiar hollow languid look of the eye, and a pale waxen aspect of the whole body, while the pulse perhaps continues of tolerable strength. These symptoms may appear while the disease has been going on but for a short time, and while the evacuations have been by no means frequent; while the affection, in short, had not been distinguished from the ordinary bowel complaints of infants."*

Billard has observed out of eighty cases of inflammation of the intestinal tube in infants at

* On Diseases of the Stomach, &c.

the breast, *thirty* of inflammation of the small intestine and colon; *thirty-six* of the disease in the small intestine alone; and *fourteen* cases of inflammation of the colon. In twenty of the first set there was bilious diarrhoea, and in all swelling and tenderness of the belly: in twelve cases bilious vomiting took place, although there was no gastritis: in all, the erythematous redness round the anus occurred; the tongue was in most cases red and dry, and the skin very hot and arid; but the pulse was rarely excited to any febrile degree, and was frequently feeble. In the thirty-six cases where the small intestine was alone engaged, there were instances of vomiting in twenty; and in fifteen of these latter the disease was situated in the ileo-cæcal region and valve. The belly was in all, at some period of the affection, tympanitic. In twenty-five there was purging of a yellowish matter, and of a substance resembling meconium; the tongue was almost always red, the skin hot, but the pulse little excited. In these cases also the erythema around the anus was generally observed. The fourteen cases of inflammation of the colon were all accompanied with diarrhoea, the tympanitis was much more slight, and in six of the cases only did vomiting take place. There was commonly great agitation, and a remarkable dryness of the skin, which was generally cold and livid. The pulse was scarcely excited.*

From these important observations it would appear that the tympanitis, vomiting, and diarrhoea are the principle signs of the inflammation of the mucous membrane of the small intestine, while in the simple colitis it is most commonly indicated by a diarrhoea, attended with but little swelling of the belly.

The absence of excitement of the pulse in these cases is a point of great practical importance, showing how guarded we should be in any case of intestinal disturbance during the period of lactation. This proposition then appears fully established, that in the infant at the breast fatal enteritis may occur without fever, and commonly without excitement of the pulse.

We must never lose sight of this fundamental principle of diagnosis as applied in particular to the enteritis of children, that *no one symptom is sufficient to point out the disease with absolute certainty*. A child may have vomiting alone, or diarrhoea alone, or colicky pains without enteritis. The occurrence of any one of these with fever is indeed a nearly unequivocal indication of inflammation; but, as we have seen, fever may be absent, and then, as to diagnosis and practice, it is to the group of phenomena that our attention is to be directed. And it should further be borne in mind that although the symptoms of vomiting, diarrhoea, and pain, taken singly, sometimes cannot be connected with a state of inflammation, yet that in most cases they are really owing, if not to this condition, at least to an excited degree of action and irritability which demands the same principles of treatment.

The sympathetic irritations which are most prominent in cases of the enteritis of children,

are those of the respiratory and nervous systems. It is of the greatest importance that these should be well understood. It appears that although at first they are not necessarily accompanied by organic changes in the parts, yet that in most cases these will sooner or later occur, and an organ, at first only sympathetically irritated, become at last really inflamed. We may then have a true revulsion of disease, or what is more common, a new visceral inflammation, in combination with the original disease. The child may then have bronchitis or pneumonia, or arachnitis, or encephalitis, together with the primary enteritis.

We have often seen children who were supposed to be labouring under severe pneumonia, from the great acceleration of breathing and fever, yet on examination by percussion and the stethoscope have found either that no disease existed in the chest, or that there was a slight bronchitis, not sufficient to account for the symptoms. In most of these cases the patients had been treated for pulmonary inflammation, and without success; and with scarcely an exception the symptoms have yielded to the application of leeches to the belly, the use of cold drinks, and the avoiding every thing calculated to irritate the gastro-intestinal surface.

The symptoms of cerebral irritation are more common as a result of enteritis in the child than in the adult. We may observe all the ordinary signs of acute inflammation of the brain, such as pain, delirium, coma, &c., and yet on dissection, this organ be found without appreciable lesion, but the digestive tube highly inflamed; and it is the opinion of some of the best pathologists, that in the infant the most common cause of hydrocephalus is a primary irritation of the digestive tube. On the other hand, we know that symptoms of abdominal disease will arise from an encephalitis; but of the two cases, the former appears to be the more frequent.

There are three affections to which children are extremely liable, the essence of which appears to consist in an inflammatory state of the digestive tube; these are the *weaning brash*, the *infantile remittent*, and *tabes mesenterica*. It is now satisfactorily proved that a diseased state of the mucous membrane is the principal pathological phenomenon in these affections. The study of the symptoms, the history of the exciting causes, and the appearances on dissection, all go to establish this doctrine, which is not new, but by no means sufficiently recognised by medical men. The first of these is manifestly an acute enteritis, produced by the change of food, and in which nature seeks to relieve the inflammation by a super-secretion; and hence the danger of the too sudden suppression of the evacuations, which lights up fever, and is commonly followed by cerebral symptoms. The phenomena of the second are all referable to a less violent irritation, but one which, if not relieved in time, will destroy life with the symptoms of *tabes mesenterica*, or if exasperated by improper treatment, may run the usual course of more violent inflammation. It may be objected to this view of the disease, that it is often relieved by the purgative plan;

* *Traité des Maladies des Enfants.*

but the reverse often occurs, and we constantly meet cases of *tabes mesenterica*, where the first symptoms were those of the infantile remittent, and in which this mode of treatment has altogether failed. This apparent paradox admits of explanation: where the first symptoms come on in children who have been over-fed, or have used highly indigestible articles of diet, the use of purgatives in the early stages may and does effect a cure by the evacuation of the noxious substances; but there is a period beyond which this treatment cannot be pushed with safety, and if the symptoms do not yield to the use of laxatives, different means must be adopted. These are means calculated to relieve inflammatory action in the mucous membrane, a state, the existence of which is proved by the appearances on dissection, which include all the effects of inflammation on the digestive tube.

The pathology of *tabes mesenterica* is not yet completely cleared up; but the following circumstances are almost decisive in favour of the opinion that it arises in most cases from chronic enteritis.

First. The mesenteric glands may become enlarged, inflamed, and suppurated in cases of acute and chronic enteritis both in the infant and the adult. *Secondly.* The great majority of cases of this affection have commenced with symptoms of enteritis. *Thirdly.* The dissections of most cases have shown an inflamed and ulcerated state of the mucous membrane. *Fourthly.* The treatment which is found most efficacious is that calculated to remove this condition of the intestine.

It is true that a few cases are to be met with where the enlarged and tubercular state of the mesenteric glands cannot with certainty be traced to enteritis; where in fact the mucous membrane does not present any trace of disease. These appear to be examples of a general disposition to tubercular degeneration of the glandular system, and are exceedingly rare as compared with the others. The absence of vascularity in the mucous membrane may in some instances arise from revulsion, such as would occur from a new and violent inflammation of some other organ; and we have seen cases where it would be attributed to mere anæmia, from the extreme emaciation of the patient. This pathology of *tabes mesenterica* was first developed by Broussais, in his *Examen des Doctrines Médicales*, in the year 1816, where he declares that the tumefaction of the mesenteric glands arises from enteritis, in the same manner as bubo in the groin arises from chancre. In this disease the fever was attributed to the engorgement of the mesentery, when in fact both of these were secondary phenomena; the true cause was not understood, and hence the uncertain and erroneous treatment of the affection.

As we should expect, this result of enteritis is much more common in subjects of the strumous constitution, or, in other words, in those where the lymphatic system is predominant. Hence the reason of its greater frequency in children, and, when occurring in the adult, in the scrofulous constitution.

Two important facts are stated by the above

author in reference to *tabes mesenterica*; one, that it has been observed to be more frequent during moist seasons; the other, that simple peritonitis will not produce the disease.

Enteritis in the adult.—In describing this form of the disease we find the same difficulty in separating its symptoms from those of gastritis, on account of the frequent combination of the two affections. We still want a series of cases, observed with a view to this particular point, which, however, is not of very great practical importance; for the existence of inflammation being recognized in the digestive tube at any point of its extent, the general principles of treatment are essentially the same.

We have already stated that the symptoms are found to vary with the portion of the tube affected; thus in the following affection the phenomena are often peculiar.

Duodenitis.—This may be an acute or chronic disease, and rarely occurs without more or less of inflammation of the stomach. Hence the term *gastro-duodenitis*. It is now pretty generally admitted that irritations of the stomach and duodenum have a powerful effect in inducing either functional or organic disease of the liver. Indeed, in the opinion of some pathologists, hepatic disease is almost always secondary to this state, a doctrine however which is too sweeping. But it appears certain, that in the notions hitherto received of affections of the liver, the influence of *gastro-duodenitis* in their production has been greatly overlooked: thus, when jaundice supervenes in the course of a *gastro-enteritis*, we may diagnosticate inflammation of the duodenum in most cases, and we shall find that to this lesion are to be attributed a great number of examples of icterus. This duodenitis is quite sufficient to produce the jaundice, independent of any mechanical obstruction to the flow of bile, or the occurrence of an acute inflammation of the liver; and the yellowness appears to arise either from the direct transmission of inflammation along the ducts, or, according to Ribes, by the branches of the porta, or, what is more probable, from the sympathetic irritation of the liver, an irritation which will produce a complete jaundice, without arising to the degree of actual inflammation of the organ. This is the doctrine of Broussais; but the fact that many cases of the most acute hepatitis will occur without jaundice, renders it probable that we must seek some other cause than the mere degree of irritation, to explain the phenomenon.

In the third volume of the Dublin Hospital Reports, Dr. Marsh details several cases of this form of jaundice, and insists on the importance of the state of the intestinal mucous membrane. In his cases, the usual cause of the affection was the drinking of cold fluids when the body was much heated, or the sudden and repeated exposure of the surface to cold after a similar state,—causes, among the most powerful in inducing *gastro-intestinal* inflammation. He there instances, also, the patients were generally ailing for some days before the jaundice occurred, and the symptoms were, those of a disordered state of the mucous membrane. The first case detailed presented

the disease completely predominant in the digestive tube. This state was pointed out by the symptoms, which were a deeply florid tongue, unquenchable thirst, epigastric tenderness, anorexia, or at other times a canine appetite, great prostration, rapid emaciation, and dysentery. We have seen jaundice apparently connected with an acute inflammation of the gastro-duodenal surface, under two circumstances. An individual is seized, after an excess at table, or other exciting causes, with symptoms of fever with decided indications of an irritated state of the stomach. There is prostration, thirst, general pain, vomiting, anorexia, foulness of tongue, diarrhoea, or constipation. The epigastrium is generally tender, somewhat full, and a dull pain is often felt in this situation. These symptoms may continue for a time, varying from a few hours to several days, when the patient becomes deeply jaundiced. At this time the heat of skin may subside, but the prostration generally continues much longer. By judicious treatment this case generally does well, but if not relieved the affection may be fatal; and in the great majority of cases, death takes place more by an extension of disease through the intestinal tract, or by sympathetic irritation of the brain, than by the production of an acute hepatitis. This appears to be one of the most frequent forms of jaundice; and the symptoms, as to intensity, may vary from a very slight to a severe disease, accompanied with remarkable indications of irritation of the nervous system. Coma is a frequent and most unfavourable symptom; and we have observed delirium and tetanic shocks to occur.

The second case in which we have seen jaundice connected with an inflamed state of the gastro-intestinal mucous membrane, was observed in a good many instances during the last epidemic of fever in Dublin. In the Meath Hospital, Dr. Graves and the writer of this article treated many of these cases, which from the dreadful severity of their symptoms, and their almost complete analogy with the yellow fever, excited the greatest interest. Of this fatal form of disease, the following description is abridged from the report of the Meath Hospital, printed for the use of the students of that institution.

"In all the cases, symptoms of gastric fever, of greater or less intensity, preceded the yellowness for a few days, and, without an exception, the supervention of the jaundice was ushered in by a great exacerbation of the symptoms of gastro-intestinal inflammation. The patient, often without any premonitory indications of the approaching danger, became seized either with spasms of the abdomen, called by the nurses "*twisting of the guts*," a name which agreed singularly with the morbid appearances found after death, or with merely hardness and extreme tenderness of the epigastrium and hypochondria. This hardness, accompanied with a knotted feel of the abdominal muscles, was speedily followed by universal jaundice, general uneasiness, anxious expression of countenance, a hurried pulse,

cold extremities, and death, commonly within twenty-four hours from the appearance of the jaundice. About one-half of the persons so affected, raved and betrayed great restlessness, while the remainder seemed in perfect possession of their intellectual faculties to the last, but at the same time appeared in a most nervous, irritable, and desponding state of mind. They could not rest for a moment tranquil, but tossed their arms about and looked at their attendants with an expression of suffering and despair. Most of them vomited, and in two cases a matter resembling coffee-grounds was discharged from the stomach and bowels. The tongue was parched, and in some instances covered with a black coating; and in one patient, the attempt to swallow produced general spasms. In all, the most exquisite tenderness of the epigastrium existed; and in several the tip of the nose became purple, giving to the countenance a truly frightful appearance, particularly when it spread from the nose to the upper portions of the cheeks. This change was preceded by pallor and coldness of the part; this was succeeded by a leaden hue, and in twelve or twenty-four hours the purple hue was complete. The toes were in some cases similarly affected; and where the patients recovered, a partial destruction of parts resulted from the disease. On dissection the appearances in all the cases were remarkably similar. The mucous membrane of the stomach and duodenum was found in an intense state of inflammation, which also extended more or less into the small intestines, where numerous recent intussusceptions were constantly found. The spleen in almost every case was greatly enlarged and softened, but in none did we find evidences of inflammation of the liver, or obstruction of the gall-ducts. Slight yellowish effusion below the arachnoid was found in several cases; and in one there was a remarkable dryness of the arachnoid. Such were the appearances in about fifteen cases of this disease. There were some cases in which general convulsions were reported to have occurred, but we could not corroborate this by personal observations. In every case a general hardness and knotted feel of the abdominal muscles, with extraordinary tenderness of the epigastrium and hypochondria, were observed. This was often so extreme as to make us suspect the existence of peritoneal inflammation; yet on dissection no instance of this lesion occurred. The bad symptoms generally came on without any indication of the approaching danger; the intestinal spasms being speedily followed by general jaundice of various degrees of intensity; and in the fatal cases death took place in a space of time varying from six to twenty-four hours. In every instance the patients suffered from extreme thirst, and there was nausea, and frequently vomiting, and in one case the genuine black vomit occurred for some hours before death."

With respect to the cause of the jaundice in these cases, we are more disposed to connect it with the severe gastro-intestinal inflammation than with any other lesion. Perhaps, the vio-

lent spasmodic action, by constricting the orifices of the ducts, might have had some effect; but the fact that many of the patients had bilious stools, and our commonly finding bile in the intestines, is against this supposition. That it did not depend on hepatitis is certain, as in no case did we find marks of inflammation in the liver. That the liver in such cases is more or less irritated is probable from the sympathy which it possesses with the gastro-intestinal mucous membrane, but in both cases this irritation is secondary, and seldom amounts to actual inflammation. In one case hepatitis was observed, but the patient was not under our care; and symptoms of suppuration of the liver, with discharge of the matter through the lungs, occurred in one of our convalescent patients. In this case perfect recovery followed. In no instance did any of the attendants of the hospital contract this form of fever; from which circumstance we conclude that the change of character did not increase the contagious nature of the disease.

In this country, where it is so usual to attribute many complaints to affections of the liver, it is of great importance that the connection which commonly exists in the relation of cause and effect, between irritations of the upper part of the digestive tube, and derangements of the hepatic function, should be carefully studied. It is true that gastro-duodenitis may exist without jaundice, or that hepatic inflammation may arise independent of disease in the mucous membrane; but it is equally true that the symptoms of gastro-duodenitis, both acute and chronic, are those commonly received as indicative of hepatic disease; and that this last affection may commence by inflammation in the digestive tube. These principles must be borne in mind; and in the treatment of such affections, if any doubt exists as to the diagnosis, it is better to give the patient the advantage of that doubt; to treat the patient for gastro-duodenitis before we have recourse to the hazardous modes supposed to be useful in hepatic disease. It constantly happens that cases of chronic gastro-duodenitis are treated as disease of the liver. This, if proper practice was pursued, would not lead to any serious injury, as the principles of treatment in both affections should be essentially the same; but where purgatives and mercurials are blindly lavished, without regard to the state of parts or the constitution of the individual, the distinction becomes of no slight importance to the safety of the patient and the character of medicine.

Inflammation of the jejunum and ileum.—It is difficult to lay down the symptoms of this affection from its frequent combination with disease in the stomach and colon; but where the disease is predominant in this part of the tube, the symptoms are generally the following: thirst, often without any vomiting, tympanitis, tenderness on pressure, pain, when present, not severe. In fact, if we abstract the symptoms of irritation at the upper and lower portion of the tube, such as vomiting and diarrhoea, we may have the remaining signs of

intestinal inflammation arising from this cause. It would, however, be wrong to conclude that vomiting and diarrhoea always point out an extension of disease to the stomach and colon; the contrary is the fact; but as a general rule the existence of these symptoms should lead us to suspect that the disease is not confined to the small intestines alone.

When the disease is severe, we commonly observe stupor, a red tongue, great thirst, tenderness on pressure, tympanitis, which is often excessive and occurring at an early period of the case, tenderness on pressure principally observable in the hypogastric and iliac regions. Diarrhoea may be present or absent, but the latter is, we believe, the most frequent case. The pulse is generally small and frequent, and the features are contracted. In a case of inflammation of the ileum in its lower third, which lately came under our notice, the abdominal symptoms were great tympanitis, pain on pressure, and thirst, without vomiting. In the commencement of the case there was some diarrhoea, but this soon subsided, and was succeeded by constipation. On dissection, the stomach and colon were found perfectly free from vascularity; but the lower portion of the ileum presented a vast number of extensive ulcerations. In this case, the absence of vomiting and of diarrhoea in the more advanced periods is extremely interesting, as connected with the healthy state of the stomach and colon. We have more than once observed, in examining the bodies of phthisical patients who never had diarrhoea, that the ulcerations and other marks of inflammation were confined to the ileum alone. In the present state of our knowledge it appears that, in cases of inflammation of the ileum, the absence of vomiting and diarrhoea seems to imply a healthy state of the stomach and colon; but on the other hand, these symptoms may occur independently of disease in these portions of the tube.

The symptoms arising from sympathetic irritation vary with the idiosyncrasy of the patient and the intensity of the disease. There may be a violent continued fever, a remittent or hectic fever, or a completely apyrexial state. We have known one case where the most prominent symptom was so violent an excitement of the heart as to lead to the belief that pericarditis and hypertrophy of the organ existed. In the Meath Hospital we have often observed increased pulsation of the abdominal aorta in these cases, a symptom which has not been sufficiently attended to. Here the excited state of the vessel seems analogous to that of the radial artery in cases of whitlow, and may be perceived even where the belly is not collapsed. Under proper treatment this subsides, with the other signs of abdominal irritation.

In the inflammation of the small intestines in the adult, cerebral excitement is generally not so prominent a symptom as in that of the child, nor is it so often followed by structural disease of the brain. It is sometimes very difficult to say whether the symptoms of irritation of the brain, under these circumstances, are really indicative of actual inflammation of

that organ. Andral relates a case where the patient, aged 35, was attacked with pain of the head, followed by great loquacity and exaltation of ideas, and other symptoms of cerebral excitement. The tongue was natural, and the abdomen *soft and not painful*. He had soon after furious delirium, and indications of strong determination to the head. Copious general bleeding, and the application of leeches to the neck produced no alleviation; and the patient expired suddenly in the midst of a general spasm. The only local symptom of an affection of the bowels during the disease was a slight diarrhœa. On dissection the brain and its membranes were found perfectly healthy; but the lower third of the ileum was in the state of acute inflammation.

Other instances of anomalous symptoms might be quoted. In many cases the disease is termed simple continued fever, and extensive destruction may be going on without the occurrence of any decided local symptom. The affection, however, should be suspected, if in addition to the general symptoms there is much thirst, tympanitis in the early stages, and irregularity of the bowels, which are sometimes constipated, or the contrary; the state of the evacuations does not afford much information, as fatal cases have occurred where they continued perfectly natural. It is in these cases that the excess of the system of purgative treatment is so liable to do injury. We believe that many patients are thus lost; ulcerative perforation being induced, or the disease aggravated and extended to the colon. We have also constantly seen the exhibition of turpentine, with the intention of relieving the tympanitis, produce the very worst consequences. As a general rule, this substance should never be exhibited in the early stage of a febrile affection where tympanitis exists. This is the disease described by Petit, under the name of the *entero-mesenteric fever*, of which the following accurate description should be borne constantly in mind. "There is at first a feeling of debility and general illness, with anorexia and irregular attacks of fever, but more often diarrhœa. The countenance is expressive of prostration and dejection; the eye dull, and the skin pale and livid, particularly about the lips and the *alæ nasi*; decubitus on the back; disinclination to motion; skin dry and harsh; torpor, and a certain degree of prostration of the intellectual faculties. The fever is obscure in the course of the day, but gradually comes on in paroxysms, without rigors or much heat, but with injection of the eye and slight delirium; there is great thirst, the teeth are dry, and the tongue is covered with a greyish paste: the stools are bilious or serous, variable in their frequency or abundance, but not sufficient to account for the prostration of the patient; belly soft and not swollen; little or no pain, but on pressure pain is felt generally on the right side, between the umbilicus and crest of the ileum: there is retraction of the lips and *alæ nasi*. The symptoms gradually increasing, we observe the cheeks to become livid, the eyes are sunk and injected, and somnolence and delirium

become constant, although the answers of the patient, though painful, are correct. Petechiæ, subsultus tendinum, and continued fever, with nocturnal exacerbations, supervene; the pulse is frequent and easily compressed; the teeth are covered with sordes, and the tongue with a brownish or black crust; the belly becomes more painful, the pain being sometimes still confined to its original situation, and without tympanitis, at other times more extended and with meteorism. The alvine evacuations become serous, fetid, and frequent, and the urine is scanty. Excoriations of the nates commence, and where the patient has been blistered there is a tendency to gangrene."

On dissection, the digestive tube is generally found healthy until we arrive at the middle of the ileum, which presents all that class of appearances constituting the *exanthème interne* of the French pathologists, the *dothin-enteritis* of Bretonneau.

This disease appears to be a common cause of what is termed an imperfect convalescence in fever. A patient, after suffering from fever for some time, becomes so much improved, that a speedy convalescence is hoped for; but in a few days it is found that strength is not returning, the pulse continues quick, and the appetite, though sometimes restored, is more often deficient and capricious. A degree of stupor comes on, and there is an occasional flush on the cheek. Under these circumstances there is often reason to suspect this disease of the ileum, which may go on insidiously to a fatal termination, or suddenly destroy life by ulcerative perforation. Dr. Cheyne describes these cases in his Report of the Hardwicke Fever Hospital for 1817, from which we extract the following important remarks:—

"In these cases the distress of the patient often bore no proportion to the danger he was in; the former was very little, while the latter was extreme. The disease would proceed without violent symptoms; nay, a patient would seem to be recovering, although without any critical discharge: he would call for full or middle diet, and for days take his food regularly. The only circumstance in his situation which demanded attention was that he regained neither strength nor flesh; he expressed no desire to leave his bed. Then his pulse again became quick and his tongue dry, and he would complain of *dull pain and uneasiness in his belly*, attended with soreness on pressure, and a degree of fulness in the upper part of the abdomen. Then came on a loose state of the bowels and great weakness: probably at the next visit the patient was lying on his back, with a pale sunk countenance and a very quick feeble pulse; his mind without energy. Then the stools (*mucous*) passed from him in bed, and the urine also; perhaps a hiccup came on; next his breathing became frequent, in which case death was at no great distance. Attempts to check the diarrhœa by astringents and opiates, or to rouse the patient by cordials, were alike unavailing; such remedies only seemed to accelerate death."

Dr. Cheyne states that in all these cases the

mucous membrane and glands of the intestine were found in a state indicating decided inflammation during life. See also *Andral, Clinique Médicale*.

The history and symptoms of inflammation of the large intestine, *colitis*, are described in the article *DYSENTERY*, to which we refer.

The foregoing view of the symptoms of inflammation of the mucous membrane of the intestine will suffice to give a general idea of the disease, of which, however, there are many other modifications. To enter more fully into these would occupy too much space, and hence we shall pass at once to the consideration of the pathological anatomy of the digestive tube. Now, in order properly to estimate the morbid, it is necessary, in the first instance, to take a view of the healthy condition of this organ.

It is now demonstrated that a great variety of shades of colour may exist in the mucous membrane, independently of any diseased action whatsoever. The situation of the part, the age of the patient, the process of digestion, and the length of time after death, will all modify the colour of this tissue. Its natural colour, however, may be stated to be greyish-white in the duodenum and jejunum; the greyish tint diminishes to the end of the ileum, and in the large intestine the colour is white. This may serve for a general description. When we examine the intestinal mucous membrane of the fetus, we find it of a rosy colour, which diminishes after birth; in youth, the white colour becomes gradually less vivid; and as the individual advances in age, the greyish tint becomes manifest.

The mucous membrane, however, is seldom met with so slightly coloured, and when we speak of the value of redness as a sign of disease, we shall examine the various sources of this change of colour.

In the state of health the gastro-intestinal mucous membrane varies in its thickness, according to the part of the tube examined. Billard has described it as most thick in the duodenum, and the thickness as diminishing in the following order of parts: the stomach, rectum, jejunum, ileum, and colon, where it is thinnest: it is obvious, however, that unless the increase or diminution of thickness be considerable, its value in a pathological view cannot be great; and, independent of intestinal disease, it may present appreciable differences. Thus, in cases of great emaciation, the atrophy of the membrane is often extreme, while in examples of mechanical congestion its thickness is frequently much increased. Louis has attempted to determine the exact depth of the mucous membrane by measurement; but this is a mode not applicable to general use. As to its consistence, this is stated to be in the direct ratio of the thickness; hence, if in those situations where the membrane has naturally the greatest thickness, we find its consistence only equal to the thinner portions, it is plain that from some cause this has been diminished. It is difficult to meet with cases on which to try the accuracy of this assertion. We have been led to doubt it more than once, but the

impediments to the investigation are very considerable; the greatest experience is required to enable us to decide on the healthy consistence of the part; and we seldom meet with the tube free from some active or passive congestion: add to this, that many other circumstances cause variations in the cohesion of the membrane, such as the presence of liquids in the tube, putrefaction, atmospheric heat, and a fluid state of the blood. The mucous follicles have lately attracted the particular attention of pathologists; and to their inflammation several remarkable disorganizations may be referred. Thus, in very many cases of intestinal ulceration, the destructive process seems to be primarily seated in these glands. Bretonneau has indeed described a peculiar disease, called by him *dothin-enteritis*, consisting in an inflammation of these glands alone; but it is still to be shown whether this disease in reality differs from other examples of intestinal inflammation. In these countries the writings of Drs. Hewett, Bright, and Abercrombie have contributed to draw the attention of physicians to these glands.

We find these bodies, in the state of health, most developed in the duodenum and stomach, and in some cases also the glands of Peyer are observed distinctly in the small intestine. This is more remarkable in children, but still their enlargement alone in the adult must not be considered as an unequivocal indication of former or actual disease.

Lastly, we have the sub-mucous and sub-serous cellular membranes, and the two orders of muscular fibres, in which tissues disease may produce a great increase or diminution of volume. The muscular fibres are compared by Andral to the muscles of white-blooded animals, and are found strongest at the pyloric portion of the stomach and in the rectum. This tunic of course appears thicker where the intestine is contracted, and, like the heart, may become atrophied in cases of general emaciation. We often indeed meet with cases where the demonstration of these fibres is a matter of great difficulty.

The natural condition of the intestine is a collapsed but pervious state. Dr. Abercrombie, in his theory of ileus, holds that the cord-like contraction is the normal condition of the part; but in this opinion he is completely singular: contraction of a muscle implies the communication of a stimulus, and cannot be considered as its natural state.

But the consideration of these tissues alone will throw little light on the physiology or pathology of the intestinal canal, if we do not take into account that its surface presents a prodigious vasculo-nervous expansion, where, in a manner analogous to the retina in the eye, or the portio mollis in the internal ear, the (sensitive) extremities of the organic nerves, and to a certain degree of those of the life of relation, are extended. It is, to use the words of Broussais, an internal sense, and thus can be understood its numerous sympathies in health and disease.

There is no organ in the body where the

determination of the value of morbid appearances is so difficult, and hence it is necessary to investigate a great number of circumstances before we can say whether the mucous membrane has or has not been in a state of disease. In general these difficulties are not sufficiently estimated; and it is to be regretted that one class of pathologists are too hasty in ascribing every change from the physiological condition to a process of irritation; in these countries, indeed, vascularity alone is too often taken for an unequivocal indication of the previous existence of inflammation, a circumstance which invalidates many of our accounts of morbid changes in the digestive system. We shall see that vascularity alone, in all its forms, does not prove the previous existence of inflammation; and that, further, the converse of the proposition will sometimes be found to be true. It may be laid down as a general principle that no morbid appearance whatsoever, taken singly, is a certain proof of the occurrence of inflammation. Even ulceration, perhaps the most certain of all, may occur under circumstances in which it is difficult, if not impossible, to trace it to an inflammatory origin.

The following are the results of inflammation on the intestine:—1. Increased vascularity, or hyperemia. 2. Increase or decrease of development. 3. Induration, or softening. 4. Ulceration. 5. Change of secretion in quality or quantity. 6. Alterations of sensibility.

Vascularity.—The great principle to be recognized in determining the value of this condition, as a proof of inflammation, is that there is nothing in its intrinsic characters sufficient to point out the nature of its origin. Many authors have described certain kinds of injection indicative of active or passive congestion; but the researches of Andral have shown that the distinctions relied on are by no means certain, and this also is the result of our experience. By a careful examination, however, of the concomitant circumstances, we shall, in most cases, be enabled to decide the question. Capillary injection, putting aside some of its rarer sources, may generally be stated to arise from one of the following causes:—1. active irritation; 2. congestion from abstraction of the venous circulation; 3. congestion from position. We may compare, by opposite characters, the inflammatory and non-inflammatory redness.

<i>Inflammatory redness.</i>	<i>Non-inflammatory redness.</i>
1. Occurring indifferently in the depending or non-depending portion of the tube.	1. Most distinct in the depending position.
2. General injection rare.	2. General injection common.
3. Without venous obstruction.	3. Commonly arising from obstructions in the porta, heart, or lungs.
4. Sometimes slight and local.	4. Generally occupying a large portion of the intestine.

<i>Inflammatory redness.</i>	<i>Non-inflammatory redness.</i>
5. With softening of the submucous cellular membrane.	5. Without much softening.
6. With alterations in the quality or quantity of mucus.	6. Without these alterations.

By means of this table, which, with some alterations, is taken from the work of Billard, we may in most cases determine the nature of vascularity occurring in the intestinal mucous membrane. The presence or absence of ulcerations, of fungoid elevations, of lymph, the state of the submucous follicles, the occurrence of thickening, and, lastly, the history of the case, will aid further in deciding the question. It has been remarked that the active and passive congestion differ in the circumstances of their formation; in the latter the injection proceeds from the large vessels, which are first distended to the capillaries, while in the former the reverse takes place. This may be a test in the earlier stages of the process.

From the consideration of the different causes of redness in this tissue, it would appear that before we conclude that vascularity in any case is an unequivocal sign of inflammation, we must in the first instance inquire whether it is not the result of the process of digestion; *secondly*, whether it may not be owing to a fluid state of the blood, as observed by Morgagni; *thirdly*, whether it arises from putrefaction, exposure to air, or the depending position; *fourthly*, whether it is the result of the congestion which occurs immediately before death in tissues abounding in vessels; *fifthly*, whether it is caused by obstructions in the aorta, heart, lungs, cava, or vena porta. Other causes of redness, independent of inflammation, are noticed, but they are not of great importance, except in the case of a patient dying in the cold stage of intermittent, where the viscera are found loaded with blood. These considerations show the difficulties that exist in the decision of this question, and should make us doubt the reports of inflammatory appearances in the digestive tube, unless made by the most experienced pathologist.

The shades of colour which are produced by a process of irritation are very numerous, but may be reduced to modifications of red, brown, slate-coloured, and black; of these, the first is most commonly, though by no means universally, the product of an acute inflammation, while the three last are nearly exclusively the result of a chronic process, in which the colouring matter of the blood, variously altered, becomes incorporated with the tissue of the mucous membrane. Of the red colour, Billard enumerates six varieties, viz. the ramiform and capillary injection, the punctuated and striated redness, that occurring in patches, and, lastly, the diffuse. Bearing in mind that all these may be the result of other causes besides irritation, and that we must look to the concomitant circumstances to decide upon their nature, we must admit, with the author just mentioned, that the first of these, consisting of a very

slight injection, must be the result of a feeble irritation, one to which the flux is by no means considerable. In the second species the injection is finer and closer, and points out a much higher degree of irritation. This is often seen in the neighbourhood of ulcerations. The punctuated redness is less common in the intestines than in the stomach; its appearance may be compared to that produced by finely sprinkling a surface with red paint, and it does not point out an intense degree of irritation. As to the striated redness, we have most usually found it in cases of chronic enteritis, where, for a considerable length of the tube, the prominent edges of the valvulæ conniventes were of a deep red colour, giving to the intestine the appearance of circular stripes. It sometimes coincides with a puriform secretion and an indurated state of the sub-mucous cellular tissue. The last two species are the most important; here the vascularity is intense, so much so as to obliterate the traces of the capillary vessels, and give to the membrane a continuous blood-red colour. They may both be the product of an acute or chronic inflammation, but generally arise from the first cause. The diffuse redness is sometimes found of great extent, and points out a most severe disease. We have often seen the mucous membrane, in such cases, exactly similar to the conjunctiva of the eye-lids in the worst forms of purulent ophthalmia. This appearance was found in most of that singular set of cases, greatly resembling the yellow fever of warm climates, which were observed at the Meath Hospital during the late epidemic of fever. It is the result of the highest degree of idiopathic inflammation; it is no longer an injection, but an active ecchymosis.

The brownish, slate-coloured, and black appearances of the mucous membrane are generally referred to a very chronic irritation. The last, indeed, is most commonly seen in cases of diarrhoea of long standing, and occurs with other indications of a profound morbid action. It is, however, seen in some cases of a high degree of acuity, as in instances of corrosive poisoning, and in the yellow fever and dysentery of tropical climates. This is important, as connected with the opinion of Broussais, where, in speaking of the black colour of mucous membranes, he holds that in most of these cases an acute had preceded the chronic state.

An important question here arises—do these appearances of inflammation always furnish an accurate measure of its intensity? We have seen that there are circumstances foreign to irritation that may increase this vascularity, such as position, mechanical impediments to the venous circulation, &c. Hence, in certain cases, the appearance of inflammation may point out a greater degree of disease than had really existed. But does the reverse ever occur? Can an inflammatory injection exist, and yet wholly or altogether disappear after death? Bichat and Broussais are both in favour of this opinion, and hold that, although no redness may be found in the part after death, yet, notwithstanding, it may have

been inflamed and vascular during life. This is a doctrine of importance from the dangerous use which may be made of it in pathology.

It is true that after death the traces of erysipelas will greatly, if not altogether, disappear in some cases, and the same has been observed with respect to the redness of a sore throat. Bichat explains this by stating that the injection of the capillaries ceases as soon as the irritation which caused it becomes extinct with the life of the patient, and lays great stress on this point in its application to morbid anatomy. But cadaveric pallor of parts previously inflamed, though occurring in some cases, is far from being a general phenomenon, and where the inflammation has been intense, as in severe cases of erysipelas or angina, the redness will remain long after death. Besides, it is scarcely logical to draw conclusions as to the viscera, from what occurs on the surface. We know that in most cases of death the blood appears to forsake the exterior, to accumulate in the interior of the body, and that this process goes on for some time previous to the extinction of life. If this post-mortem emptying of the capillaries went on in the mucous membranes as we see it in the skin, redness of these tissues should be as rare as that of the skin; but the contrary is the fact. We may admit the possibility of this subsidence of the appearances of inflammation of the mucous membrane in very slight cases; but looking at the phenomena of death in general, we must hold it more probable that these appearances will be augmented rather than diminished on the cessation of life.

But there is one cause for the want of redness even where a high degree of irritation has existed in parts, namely, the supervention of inflammation in other viscera, which, from its excess, causes an actual revulsion. Thus, when a bronchitis subsides on the supervention of a fatal diarrhoea, we may find the bronchial membrane free from vascularity; or *vice versa*. This cause is alluded to by Billard. In the severe gastro-catarrhal fever, we constantly observe alternations of severity in the abdominal and thoracic symptoms, and more than once we have seen cases in the early stages of which the symptoms of enteritis were severe, but subsiding when the thoracic irritation became intense, and have found the *intestinal membrane pale, although ulcerations and other disorganizations were present*.

With respect to the relative frequency of inflammatory redness in different parts of the digestive tube, it is agreed that the stomach and lower part of the ileum are most commonly engaged, and it is remarkable that the two affections often coincide. This has led to the term *gastro-enteritis*; a term, however, which cannot be adopted, as the coincidence is by no means universal, and as by a too great generalization, it leads to an erroneous view of the disease. The order of frequency, as given by Andral, in the remaining portion of the intestine, is as follows:—the cæcum, colon, rectum, duodenum, superior portion of the ileum, and, lastly, the jejunum.

Increase of development, or hypertrophy of the coats of the intestine, is generally the result of a process of chronic irritation; the thickening of the mucous membrane which occurs in acute affections being more apparent than real, and owing to vascular turgescence merely, while that in the chronic cases is a true hypertrophy, the result of an increase of nutrition. The parts which, in acute diseases, are most usually increased in bulk, are the mucous membrane, and the glands of Peyer and Brunner, while all the constituents of the tube may become hypertrophied in the chronic enteritis. The thickness of the sub-mucous cellular tissue is rarely altered in acute, but commonly in chronic cases.

When the mucous membrane is hypertrophied, we find the change to be circumscribed, or the contrary, and seldom observe the tissue equally thickened. In the large intestine we have commonly found the mucous membrane elevated into numerous nodules, of about the size of a pea, between which ulcerations, or a lesser degree of hypertrophy, existed. Numerous varieties of these elevations are described by authors. In cases of this hypertrophy the consistence is generally increased, and the colour dark; and it rarely happens that the change is confined to the mucous membrane alone; it occurs much more frequently in the large than the small intestine.

But of the forms of hypertrophy of the intestinal tunics, that of the sub-mucous cellular tissue is the most important. In this state we find it a dense white layer, sometimes more than two or three lines in thickness, presenting a distinct fibrous structure, and giving to the whole tube a remarkable feeling of thickness and rigidity. The induration is often so great as to cause a grating sound when the intestine is divided by the scissors. The principal seat of this alteration is the sub-mucous, but we have often seen it to engage also the sub-serous cellular membrane. It is in the large intestine that the change is most usually observed, where, after chronic dysenteries, it is found in conjunction with other disorganizations. In the small intestines, however, it may be met with, generally partial, and in the vicinity of old ulcerations; but in a few cases of severe chronic enteritis we have found hypertrophy of the whole cellular membrane from the pylorus to the anus. These were cases where severe symptoms had continued for months, the patients presenting that singular tenacity of life observable in greatly emaciated subjects.

To this change is to be referred most of the cases of organic stricture of the intestine: indeed, when examined anatomically, we can see in this disorganization nothing but a partial hypertrophy of this tissue, generally traceable to a process of inflammation in the mucous membrane. We say generally traceable, for although in the present state of the science we must attribute most of these cases to this cause, yet in some it may arise from a morbid process, not originating in or extending to this tissue. These, however, may be looked on as exceptions to a general rule, and, as far as we

have seen, seem connected with a disposition to cancerous degeneration of the cellular membrane, both in the solid and hollow tube.

This alteration, as a result of chronic enteritis, may be met with in all ages, from the infant to the octogenarian. It is, however, stated to be most common between the ages of thirty-five and sixty-five, and that between puberty and the first of these periods it rarely occurs. We have already alluded to the atrophy of the intestinal tube, a change which may be confined to the mucous membrane alone, or engage all the coats of the intestine. How far atrophy can be referred to a process of inflammation does not yet appear to be determined, as there is a difficulty in the circumstances of the general nutrition being impaired in these cases. We have seen ulcerations coinciding with an atrophy of the intestine, but in all these cases great emaciation had existed some time previous to death. This atrophy appears always to coincide with a softened state of the mucous membrane.

Change of consistence is always admitted as one of the consequences of inflammation, and, with a few exceptions, the rule, that a chronic irritation tends to harden, while an acute tends to soften parts, is generally found to be true. In the gastro-intestinal mucous membrane the latter part of this proposition is, in our experience, always true; but we cannot make this statement with respect to the first part, the fact being that an indurated or softened state may result from a chronic enteritis, though the first effect is the most usual. We have found the indurated state of the mucous membrane under the two following circumstances: first, in cases of chronic dysentery, where the mucous membrane of the colon was hypertrophied and ulcerated; between the ulcerations the consistence of the membrane was greatly increased: secondly, we have seen, in cases of scirrhus degeneration of the subjacent cellular tissue, the mucous membrane of the small intestine singularly changed; it resisted traction remarkably, had lost the velvety feel, and gave to the touch precisely the sensation that is presented by the vagina in cases of advanced cancer of the uterus. The parts most indurated appeared to be the projecting edges of the valvulae conniventes, and the whole of the membrane was studded with extremely minute and hard granulations.

We now come to the consideration of the inflammatory ulcerations of the intestine. When we compare the bronchial and intestinal mucous membranes in their pathological states, we must be struck with the difference in the frequency of ulcerations in these tissues. In the first, they are of rare occurrence, in the latter extremely common; in the first we constantly see an acute or chronic inflammation without a trace of ulceration, in the latter this effect constantly results from both these forms of disease. This difference may be explained by considering the great predominance of the mucous crypts in the gastro-intestinal system, as compared with the respiratory. In fact, for the healthy performance of the re-

spiratory function, a very small quantity of mucous secretion is required, but the reverse is the case as to the function of digestion. We must also take into account the greater exposure of the digestive canal to chemical and mechanical stimulation.

The circumscribed ulcerations of the intestine may be divided into two classes, those affecting the mucous membrane alone, and those engaging both this tissue and the mucous glands. The first of these species is the rarest; the second is extremely frequent, and is called the follicular ulceration.

As the minute description of these ulcerations is not of much practical importance, we shall not enter into the subject here, and shall merely refer to the late works on pathological anatomy, and to the article *FEVER*, for complete information. Suffice it to say, that they are extremely frequent, and that their varieties, with respect to number, appearance, and accompanying disorganizations, are infinite. The cases in which they are most frequently met with are the following:—typhous fever, with predominance of gastric symptoms; dysentery; long-continued diarrhoea; stricture of the intestine; infantile remittent; tabes mesenterica; tuberculous phthisis, and in cases of hypercatharsis, from an over-dose of purgative medicine.

In the great majority of cases these ulcerations do not perforate all the coats of the intestine, but in a few this does occur, and the result is most commonly an effusion of the contents of the intestine into the peritoneal cavity, and consequent rapid peritonitis. Two important facts seem ascertained with respect to these perforating ulcers, *first*, that they are almost always the result of disease in the mucous follicles, and, *secondly*, that they are more liable to occur from acute and circumscribed than from chronic and extensive disease. We may explain this by considering, that in the chronic ulcerations the cellular membrane at the base of the ulcer is generally more or less indurated and hypertrophied, which gives it an increased power of resistance to the ulcerative process, and also that from the general emaciation which commonly occurs in such cases, the tube is in a state of anæmia, where, of course, inflammatory action will occur with a lesser degree of activity. The extent of the disease, by diminishing its intensity in any particular point, may also contribute to this result.

The situation of the perforating ulcer is remarkably similar in most of these cases. In the ten examples recorded by Louis it occurred somewhere in the last twelve inches of the ileum, and out of the same number observed by us in the Meath Hospital, but one instance occurred where it was in a different situation, namely, the cæcum. This ulcer was also remarkable in not presenting the follicular character. We may remark, that these observations as to the situation of the perforating ulcer apply principally to the acute cases.

Effusion of the contents of the intestine is not a necessary result of this lesion, as the serous covering of the adjacent fold of intes-

tine may form adhesions round the edges of the ulcer, and thus constitute its base, or a direct communication may be formed between two portions of the tube previously in contact. In both these cases the occurrence of general peritonitis is not a necessary consequence. (See the article *PERITONITIS*.)

Treatment.—We shall first examine the treatment of the disease as it occurs in the *infant and child*. In most instances of this affection we may admit of two stages, indicating a different treatment; the first, where the antiphlogistic method is to be our chief resource; the second, where revulsives and the cautious use of the tonic plan are indicated.

In this affection it is not often necessary to have recourse to the lancet, although such a case may arise, as where the symptoms are violent, the fever high, and the constitution healthy and robust: here venesection cautiously performed will generally be followed by the best results, and be the best preparative for other measures. In these countries a prejudice against bleeding in the child sometimes exists, but we believe that it is unfounded. More than once have we seen the symptoms continuing with violence, and even resisting the employment of leeches, until blood was taken from the arm; then the remedies which had before failed acted well, and recovery was progressive and ultimately complete. When we cannot succeed in opening a vein in the young infant, the mode from which most advantage is derived, is the application of a leech or two to the back of the hand or foot, and afterwards plunging the part into warm water; in this way we can obtain a considerable quantity of blood, and the hemorrhage is easily controlled by a bandage.

If the bowels should not be open, it is advisable to procure a moderate evacuation of the tube, but no violent or irritating purgative is on any account to be given, and we should trust chiefly to the mildest laxatives and to injections, which are almost always productive of the best effects. It sometimes happens, after the above means have been employed, that the disease appears either to be subdued or greatly lessened in its intensity; the tongue cleans and the fever is much diminished; but in more violent cases this alteration is scarcely perceptible, and then no time is to be lost in applying leeches to the belly. This may be done at all ages, and is without exception our most powerful remedy in most cases. The number must be proportioned to the violence of the disease and habit of the patient. We have seen three or four leeches applied to the abdomen of an infant of twelve months old with the best effects; but, as a general rule, a leech for every six months of the child's age up to that of four years would not be excessive. These may be re-applied according to circumstances, for it often happens that symptoms, scarcely if at all affected by the first application, will subside on the second. The prejudice against the use of leeches in the diseases of children is fast wearing away; in fact, the only objection

of weight is the difficulty of arresting the hemorrhage. For this purpose the simplest and most efficacious mode is the application of the solid nitrate of silver to the leech-bite. A stick of caustic should be cut down to an extremely fine point, and being pressed to the bottom of the wound, (which should be previously dried by a little lint,) and given a turn or two, is then to be withdrawn: this seldom fails to stop the bleeding at once.

The internal remedies from which we have seen most advantage are the combination of a mild mercurial with Dover's powder, and, in the next place, gummy solutions. The hydrargyrum cum creta, with Dover's powder, may be given in repeated doses, proportioned to the age of the patient. An over-degree of narcotism is, of course, to be avoided; but it frequently happens that, after a decided opiate effect has been produced, the symptoms of intestinal irritation greatly subside. It is a remedy that requires caution in its exhibition, but one of great utility. It sometimes constipates, and when this occurs it may be omitted, and a small quantity of castor oil or manna may be given, assisted by an emollient injection; and when these have performed their office, the remedy can again be resumed.

In some cases it may be desirable to produce a decided mercurial action. To excite this in the child is a matter of great difficulty, and our own experience leads us greatly to prefer the external application of mercurial ointment to the administration of much calomel. We have known a mercurial plaster, or dressing a blistered surface with the ointment, answer remarkably well. But in every case we should endeavour to remove the disease without the exhibition of a great deal of mercury, as its effects in children of an unhealthy habit are often most formidable.

Blisters have been used in this disease with various results, and if they are not employed until the advanced stages of the affection, and are employed only as secondary to general or local bleeding, they will often be useful. In young children they should never be left on for more than two or three hours, and in older patients they should be removed as soon as uneasy sensations are perceived from them. It is always advisable to insert a piece of silver-paper between the blister and skin. As a general rule, it may be stated that blisters should not be used when the skin is very hot, the fever high, and the patient in a state that would admit of general or local bleeding. Perhaps they may be more safe in those cases where the mucous inflammation has arisen from the suppression of a cutaneous irritation.

There is a difference of opinion about the utility of the warm-bath. We have found it chiefly useful in the advanced stages, and where there is much diarrhoea; but it appears to us that the practice of diligently fomenting the belly is as serviceable, and one which may be used in all stages.

The little patient must be kept on an extremely strict regimen, and every thing that could possibly disagree must be avoided.

A strict regimen is peculiarly necessary in the enteritis of children, as the slightest irregularity in this respect may produce a fatal relapse. Cold water may be freely allowed and may be slightly acidulated, according to the feelings of the patient; in addition to which we have always been in the habit of administering in some quantity a solution of gum arabic, and have seen, in cases where the disease predominated in the lower portion of the tube, the most decided benefit from it. But after the first week of the disease it becomes necessary to attend to the support of the patient. Many children are lost by the practitioner neglecting this point. Small quantities of the farinaceous foods, milk and water, and very weak chicken-broth may be used, and their quantity regulated by the effect on the symptoms. These should be given at stated intervals of time, say every third hour; and it may even be necessary in the advanced stages to administer a little wine, particularly when the skin is cool, the countenance sunk, the mouth covered with sordes, and the stools involuntary. Should this excite a too strong re-action, it can be omitted, and again resorted to if necessary. Great attention must be paid throughout to prevent excoriation of the back, and to preserve the warmth of the extremities, and the apartment should be kept at a regulated temperature. This, among its other advantages, will tend to prevent the liability to bronchitis, which disease sometimes carries off the patient after the subsidence of the enteritis.

Enteritis in children is commonly mistaken for worms, and thus improperly treated. Drastic purgatives are lavished; the increase of symptoms and the marasmus are attributed to the persistence of the worms; until at length typhoid symptoms appear, or the child falls into the state of *tabes mesenterica*. These cases are always of the worst description from obvious reasons. It would appear that when the disease arises from the use of indigestible food, or from constipation, purgatives cautiously exhibited at the outset are useful; but if after the unloading of the bowels the symptoms continue, it is a sign that something more than mere irritation from the presence of noxious substances exists, and that we must treat the disease as one of enteritis. These remarks apply equally to the enteritis of the child and adult. The indiscriminate system of purging in all cases is the opprobrium of British medicine, for it is a fact that, since the writings of Hamilton and Abernethy, too many practitioners have had, in the treatment of digestive derangements of most kinds, but two objects in view, the one, of giving doses of purgative medicine, the other, the quantity and quality of the fecal discharges; while the gastro-intestinal surface, that prodigious vasculo-nervous expansion, has been wholly unheeded and forgotten.

Cerebral symptoms often supervene in the course of this affection, and it is sometimes difficult to say whether they proceed from actual disease of the brain, or merely indicate a sympathetic excitement not amounting to

positive inflammation. But we know that sympathetic irritation cannot long exist in so delicate an organ as the brain without producing disease, and further, that we cannot tell when this change takes place. Hence the safe mode of proceeding is always to treat the cerebral symptoms as if they really proceeded from encephalitis. In such a case it is generally unnecessary to use the same degree of vigour in treatment as if the disease was idiopathic inflammation.

When the disease occurs in *the adult*, the chief remedy will be found to consist in the detraction of blood generally and locally, but particularly the latter, unless in cases where the symptoms run high and threaten peritoneal inflammation. Here the lancet is never to be neglected, and its use must be repeated frequently if the violence of the disease is not subdued. Dr. Abercrombie recommends the practice of following up the first bleeding by smaller detractions of blood, so as to keep up a decided impression on the system. It seems, however, that in most cases we may look on general more as a preparative for local bleeding, which, when properly performed, is a means of extraordinary value. Facts, however, oblige us to admit the efficacy of general bleeding alone in reducing inflammations of the mucous membrane.* When the disease exists in the small intestine, we have always found most advantage from local bleeding. It may be performed at various stages of the disease, even when there is great adynamia, and will seldom disappoint the practitioner. Leeches should be applied abundantly round the navel or to the ileo-cæcal region, and the hip-bath used when they fall off. If the symptoms do not yield at once to this treatment, the leeching is to be boldly repeated, and a large poultice applied over the belly. The bowels are to be gently opened by the mildest laxatives, and emollient injections should be frequently given.

The most distressing symptoms in this disease are the vomiting, thirst, tympanitis, and diarrhoea. It is often very difficult to allay the first of these. We have found nothing so efficacious as the application of a dozen leeches to the epigastrium, and the liberal use of iced water, or even plain ice, which may be given nearly ad libitum. It is a most grateful and important remedy, and one from which we have never seen any unpleasant results. In the more advanced stages of the disease we have constantly applied leeches to the epigastrium, though in smaller number, and have seen that assemblage of phenomena which constitute the typhoid state speedily disappear after their use. In addition to this, we have in the hospital often applied a small blister over the region of the stomach, and afterwards sprinkled the surface with a little acetate of morphia, a practice which, in some cases, succeeded remarkably. Effervescent draughts, with the carbonate of soda or ammonia, may be exhibited, but not in too great quantity, as

violent diarrhoea and exasperation of all the symptoms may be the result of this excess. Lastly, opiates, and, in some very advanced and low cases, stimulants may be used with advantage. The thirst may be moderated by the use of cold acidulated drinks, such as lemonade, the cream of tartar solution, and tamarind-tea; but let it never be forgotten that the means best calculated to remove these symptoms are those calculated to reduce the inflammatory action. The tympanitis, when it arises, is a symptom commonly maltreated from ignorance of its pathology. Occurring in the early stages of the disease, it is generally in proportion to the intensity of the inflammation. It is a distressing symptom, and hence practitioners are over-anxious for its removal, and are tempted to exhibit turpentine. From witnessing a great number of cases where this practice has been pursued, we feel certain that the exhibition of turpentine or analogous remedies for the removal of tympanitis in the early stage is a practice pregnant with danger. It often, indeed, renders the belly flat; but this apparent advantage is commonly followed by an increase of the other symptoms; and the tympanitis is sure to return. If the symptom be not severe, its presence should not make us modify our treatment; if it is excessive, it becomes a sign for increased activity in means calculated to reduce the inflammation without endangering the safety of the patient. In addition to this, stimulating injections, where there is not tenesmus, may be used, and enemata of cold water in all cases. In the stages of the disease, however, where depletion can no longer be practised, the use of turpentine is sometimes successful, a circumstance reconcileable with our knowledge of the effects of stimuli in the advanced periods of mucous inflammation.

Nearly the same remarks apply to the diarrhoea. The exhibition of astringents in the early stages is generally followed by the worst effects, a circumstance favouring the doctrine that the secretion is the relief of the inflammation; but when the powers of life are low, and the disease not acute, we must moderate it. This is best done by the warm-bath, a flannel roller, the occasional application of a blister to the belly, anodyne injections, and the use of small doses of Dover's powders, with or without rhubarb. Where the diarrhoea was severe and the patient much depressed, we have often used large doses of opium with the best effect.

The remarks as to revulsion, regimen, &c. which we made in treating of the enteritis of children, apply equally in this form of the disease.

(W. Stokes.)

EPHELIS (from $\varepsilon\phi\eta\iota$ and $\sigma\lambda\iota\sigma$, *sol*), a genus of diseases of the skin, of the order *macule*, (see the article *MACULE*.) characterized by discolorations, varying from dark brown to greyish yellow, and presenting great diversity of form, from small distinct points, sometimes scattered, sometimes grouped, to large confluent or continuous patches.

* See Cheyne's Report on Dysentery.

Syn. Maculæ fusæ (*Plenck*); Ephelides (*Alibert*).

We use the term *ephelis* in the extensive sense which has been given to it by *Gorræus*—"non quod à sole tantum vitia illa in cute contrahuntur, sed quod à reliquis inducta causis, similem asperitatem et colorem habeant;"* although we do not altogether agree with *Bateman*,† that this acceptance of the term is sanctioned by the authority of *Hippocrates*,‡ for he appears to have distinguished between *lenticula* (*φαιδς*) and *ephelis*, both included in this definition. *Celsus* went farther; he not only distinguished between *lenticula* and *ephelis*, but also between *lenticula* and the *φαιδς* of the Greeks.§ These distinctions were lost sight of, and the term *ephelis* was made more comprehensive by *Oribasius*,|| *Ætius*,¶ and *Actuarius*.** *Sennertus*†† revived the ancient distinctions, in which course he was followed, more or less, by *Sauvages*, *Lorry*, and *Plenck*; but whilst the first of these raised distinctions on one hand, he removed them on the other, and thus included under *ephelis* morbid appearances which have no relation to it. This last is also the error of *Alibert*, who, in his order of *Ephelides*, includes scorbutic blotches.

These affections of the skin seldom demand or deserve, on their own account, the attention of the practical physician; but as signs of internal disorders they sometimes afford very valuable diagnostic evidence, as much as *erysipelas*, *urticaria*, *prurigo*, and many other eruptions. And we perfectly agree with *Alibert*, that they afford matter of interesting research to the physiologist, shewing how the integuments may become discoloured, and revealing in some manner, by external appearance, the alterations to which the human body is subject. Besides, it is shewn in the study of the natural sciences that the most trifling facts may be useful, because, being connected by an almost imperceptible chain with phenomena much more important, they sometimes indicate, sometimes explain them.

The process of the formation of the *ephelis* is unknown. It is not the result of any particular alteration of the epidermis, but some modification of the pigmentum of the skin which science is not yet able to explain. It would seem sometimes to be a consequence of an inflammatory action; it is frequently accompanied with signs of a determination of blood to the skin, but neither of them are constantly observed. It is very variable in its progress and duration, sometimes developing itself fully and extensively in the course of a night, sometimes very slowly; sometimes it is permanent, continuing indelible

for several years, and sometimes it disappears after a single bath or lotion.

Not having found any previous arrangement of this genus which satisfactorily comprehends all its varieties, we propose considering it under two species, viz. 1. *Ephelis lentigo*; 2. *Ephelis diffusa*.

1. *Ephelis lentigo*. *Syn.* *φαιδς* (*Hipp. et Græc.*); *Lenticula vellentigo* (*Latin.*); *Ephelis lentigo* (*Sauvages and Alibert*); *Lentigo* (*Lorry, Plenck*); *Lentigo ephelis* (*Frank*); *Sommersprossen et Sonnensprossen, Sommerflecken* (*Teutonicæ*). Freckles.

An eruption of small minute spots of a fawn, yellow, or brown colour, sometimes disseminated, sometimes in clusters, unaccompanied with any pain or itching.

This eruption presents itself under two circumstances; it is either hereditary, a natural deformity of the skin, or it is purely accidental, the result of exposure to the sun's rays. This affords the division of the species into two varieties: a. *Ephelis lentigo materna*. b. *Ephelis lentigo æstiva*.

a. *Ephelis lentigo materna*. *Tâches de rousseur* (*Gallicæ*). The well known lenticular eruption, forming, as it were, part of the natural complexion of yellowish or reddish-haired persons, who are, besides, distinguished by the strong odour exhaled by the secretions of their skin. (*Alibert*, Pl. xxvi.) It is more rarely, but sometimes, observed in persons of a fair and delicate skin with dark hair and eyes. The colour and shade of the eruption bear always a near relation to the colour and shade of the hair, being sometimes as dark as coffee or chocolate, and sometimes of a light yellow. The eruption is not confined to the parts of the body exposed to the light and air, but sometimes occupies the whole surface; neither does it disappear in winter. It is to this variety that the French term, "*tâches de rousseur*," strictly applies.

They who would attempt to cure this deformity would deserve a severer rebuke than that of *Celsus*—*Penè ineptia sunt, curare varos, et lenticulas, et ephelidas*. But the importance attached by the fair sex to this discoloration has not left the matter unattempted—*eripi tamen feminis cura cultus sui non potest*. It would be idle to repeat the various means which have been used for this purpose. They who are curious in such matters may consult *Ætius*, lib. 1. serm. 4. cap. ii.; lib. 4. cap. xiii.; *Haly Abbas*, lib. 9; *Avicenna*, Fen. 7. tr. 2; or the monograph of *Bender* on *Cosmetics*.*

b. *Ephelis lentigo æstiva*.—*Syn.* *Ephelis*: *Maculæ solares* (*Plenck*); *Ephelis a sole* (*Sauvages*); *Nigredo a sole* (*Sennert*); *lentigo æstiva* (*Jos. Frank*); *Le hâle* (*Gallicæ*). Sun-burn.

To this variety exclusively belongs that very common lenticular eruption, chiefly observed in young females of a delicate complexion, supervening with the summer and disappearing

with the winter, and confined to those parts of the body exposed to the sun and air.

This eruption is purely a local affection; the radiation of the sun upon the exposed surface of the skin, more particularly observed in youth, being the only cause of this eruption; hence those occupied in the labours of the field, mountaineers, those accustomed to expose themselves bareheaded, or persons pent up and etiolated in cities, when they visit the country, are particularly subject to it. This cause may operate quickly or slowly, and the colour of the freckle always bears some relation to the complexion and colour of the hair.

When this eruption does not cease with the removal of its cause, or with seclusion, or the use of veils or shadowing hats, its disappearance may be accelerated by the use of certain local applications; and, indeed, even under the influence of its cause, it may be much moderated by them. Every country supplies some of these nostrums, chiefly domestic, the results of vulgar experience. They are most of them more or less stimulating, but some of them soothing and demulcent. The best practice is for the bland and emollient application to precede that of the stimulating. The former consists of such things as vapour (that of milk was an especial favourite); emulsion of the seeds of cucumbers or melons, or pomatum prepared from those seeds; decoction of the flour of lupines, of tares; the boiled pulp of the roots of narcissus; paste of bitter almonds, and such like. The latter consisted of poultices made of the seeds of cauliflower, or of the flour of tares or lupines macerated in vinegar, or the bulbs of the narcissus boiled in vinegar, to which was added some of the roots of the wild cucumber, bryony, and the leaf-stalks of the fig-tree; the juice of the house-leek, the leaves of the cherry-tree, the leaves of ivy, the ashes of the sepia, the bulb of the Illyrian iris, and the bulbs of the lilly, mixed with nitre and honey. Ox-gall has been always celebrated. The favourite remedy in the harem of Turkey is said to be a pomatum prepared from balsam of Mecca, the seeds of the garden cucumber and cerussa: in the north of Europe, Goulard's lotion, the juice of sorrel, lac sulphuris macerated in the juice of currants, solution of sulphates of zinc or copper, lemon juice, oxycrate with camphorated mixtures, rubbing the part with a slice of lemon or of a sour apple. But all these various means may be more conveniently represented by any weak alkaline solution,

(R. Liqueur. potassæ, 3i.

or a diluted spirit or acid lotion.

The following were favorite formulæ much vaunted:

2. *Ephelis diffusa*, an eruption of distinct or confluent large, irregular, round patches, of a tawny, yellow, or brown colour.

This form of ephelis may be symptomatic as well as idiopathic.

a. *Ephelis diffusa symptomatica*.—*Syn.* Maculæ hepaticæ (*Sennert**); Hepatizon (*Var. Auct.*); vitiligo hepatica (*Sauvages*); kelis fulvescens (*Swediaur*); Ephelis (*Plenck*); Chloasma (*P. and J. Frank*); Ephelis hepatica (*Alibert*); chaleur du foye, tâches hépatiques (*Gallicæ*); Leberflecke (*Teutonice*).

This eruption, which is generally preceded by a slight itching, is of the colour of saffron or rhubarb, sometimes pale like the withered leaf; it is most commonly situated on the neck, sometimes entirely surrounding it like a cravat; on the abdomen, especially on the region of the liver, over the kidneys, or on the groins; sometimes on the forehead. The patches are at first distinct and distant, but extending gradually they run into each other, or they form groups more or less numerous. (Plate LXXIX. *Bate-man's Delineations*; Plate XXVII. *Alibert*.) They are sometimes slightly elevated, and terminated by a desquamation of fine thin yellow scales assuming somewhat of the nature of pityriasis, the *pityriasis versicolor* of Willan, the *chloasma pseudo-porrigo* of Frank; and sometimes they are complicated and coincident with the wheals of *urticaria*. The itching is sometimes much greater than that of pityriasis; it is much influenced by the weather, and increased by being heated by exercise. *Alibert* has observed that the patches of ephelis are not transpirable, but very dry, whilst the surrounding skin is soft and moist.

This variety of ephelis is sometimes permanent and sometimes transient. In the first state it is met with chiefly in men of close sedentary habits, presenting large blotches upon the abdomen, sometimes entirely encompassing it as a belt, or large patches over the shoulder. Some of these spots it is not difficult to disperse, but some remain indelible. In the second state they are more frequently observed in women in the form of isolated circular patches, appearing and disappearing very rapidly, sometimes in the course of half a day; they are chiefly seated on the back part of the neck, on the throat, breast, and hypochondria. In some women they return at every menstrual period; in others they co-exist with suppression of the catamenia, the *chloasma amenorrhæum* of Frank; they afford sometimes a sign of conception,† appearing as superficial spots as broad as the hand, of a pale yellow or dark tawny colour, without roughness or inequality, most frequently on the forehead, breasts, and abdomen, occasionally disappearing at the end of the first month, but frequently continuing during the whole period of

* Lib. 3, pars iii. sect. 1. cap. viii.

† *Hippoc.* de morbis mulier. *Sennert.* Pract. lib. 5, pars iii. s. 1. c. 2.

gestation, and not always disappearing on parturition—the *ephelis gravidarum* of Plenck and Sauvages, the *chloasma gravidarum* of Frank. It is remarked that those who are most indisposed by pregnancy are most liable to this eruption. In men they are observed sometimes precursive of a hemorrhoidal flux. In women, the itching attendant upon them is always increased on the approach of the menstrual period. Sauvages says he has not unfrequently observed the eruption of ephelis to be periodical after tertian and quartan agues, and sometimes an attendant of *nostalgia*.

Besides the state of body just mentioned as predisposing to this variety of ephelis, it is frequently accompanied by a serious disorder of the function of the liver, but most constantly connected with chronic irritation of the stomach and intestines. In such cases it is sometimes suddenly excited by any trifling vexation, chagrin, or contrariety, or by protracted application or study.

The treatment of this eruption consists in the appropriate cure of the primary disorder of which it may be a symptom: when connected with the natural functions of the body, it can only be remedied by promoting their more easy performance; when symptomatic of uterine disorder, it demands the treatment of amenorrhœa or dysmenorrhœa, when of chylopoietic disorder, its cure falls under dyspepsia. In general, mild cooling cathartics, light diet, sulphurous preparations, particularly the sulphurous mineral waters, as those of Harrogate, Cauterets, &c., and if necessary, a mild alterative of some mercurial and antimonial preparation, constitute the internal remedies. The best external preparations are sulphurous baths, particularly of the natural warm mineral waters, the warm sea-bath, or locally a lotion of sulphuret of potass.

R Potass sulphuret. ʒi.

Aquæ lib. ii. fiat lotio.

Camphorated vinegar is also a good local application. When the spots are indolent, friction, and, if not extensive, a sinapism applied for a short time, or a poultice of soft soap, have been known to succeed.

b. *Ephelis diffusa idiopathica*.

We only notice this variety that we may not omit two forms of ephelis enumerated by other writers.

1. *Ephelis ignealis* (Sauvages); ephelis spuria (P. Frank); lentigo ab igne (J. Frank); taches de brûlure (Gallie). The mottled spots produced by artificial light and heat, observed on the legs and arms of those who bask over the fire, or on the legs and thighs of women who during winter make use of the chauffepié.

2. *Nigredo a sole* (Sennert); fuscado cutis (Plenck); ephelis umbrosa (J. Frank); die braune haut (Teutonic). The dark, swarthy, brown colour of the skin acquired by Europeans who inhabit tropical climates, or by those exposed to salt-water and hard weather.

(T. J. Todd.)

EPIDEMICS. Epidemic diseases (*νόσοι ἐπιδήμοι*, from *ἐπί*, among, and *δῆμος*, people,) are those which attack a number of persons, in any city, district, or country, about the same time or season. They are generally uncertain in their recurrence. When they produce great mortality they are called pestilential. Epidemic diseases are chiefly of the acute or febrile class, some of which are apt to prevail in spring, some in summer, and some in autumn; some in one country, and some in another.

Endemic diseases are found to prevail more or less at all times, in districts where the local causes act, and among people exposed to their operation: but the production of epidemics, inasmuch as they depend on circumstances of a wider range, which are in their nature variable, (such as the vicissitudes of heat and cold, the prevalence of particular winds, the varieties of season and weather, as to drought and moisture, the deficiency or deteriorated quality of different articles of common food, and other things,) is liable to great uncertainty in almost every part of the world.

As epidemic diseases are above defined, they do not exclude some that are contagious. Distinctions have been attempted to be established, it would appear unwisely, between epidemic and contagious diseases. An attentive and unbiassed observation of facts removes these unphilosophical distinctions. Many epidemic diseases appear, under certain circumstances, to be communicable by contagion; and some diseases, avowedly contagious, prevail epidemically. Facts, in all ages, would seem to show that most epidemic diseases have a tendency to spread by intercourse with those exposed to the same causes of disease, and thus predisposed to it. This tendency has been made too much of by systematic writers, in some cases; and in other cases, too little. No epidemic disease either attacks simultaneously, or rages with indiscriminate violence, among all classes, in any community; and no contagious disease attacks every one who is fully exposed to its influence. Epidemic diseases, whether contagious or not, have their assigned laws. Even when highly pestilential and destructive, they observe stated seasons, and periods of rise, increase, and decline. When their attack is most sudden and general, they pass over a large proportion of the community. In the former case the disease loses its malignity; in the latter, some constitutions are proof against the common destroyer, without any apparent immediate intervention of art.

It is a rare thing that any one form of epidemic disease rages alone, that is, without being preceded or followed by another. Different forms of epidemic diseases usually succeed each other in a series, either in the same year or in different years: and this is called an epidemic constitution. Sydenham was of all English physicians the chief observer of these phenomena, and was pre-eminently entitled to the appellation of the English Hippocrates: he was of too honest a nature to let preconceived opinions and mere arbitrary names of diseases

prejudice his correct observation of their changes from one season to another.

Viewed practically, epidemic diseases require minute and cautious observation on the part of the physician; for diseases of the same name, as Sydenham remarked, often require different treatment at the beginning of the epidemic and at the decline; as they require different treatment in different countries, and frequently in the same, under different epidemic constitutions. The diseases of an epidemic constitution will sometimes shew an unusual tendency to one part of the system, and sometimes to another; as they will affect a particular type. This tendency is either to the skin, or the head, or the chest, or the stomach and bowels, and often continues for many months, or even years, in the reigning diseases. It was remarked that at the time the sweating sickness raged in England, other diseases assumed the sweating tendency.

It is much to be lamented that many things stand in the way of accurate knowledge on this subject. It is comprehensive, and surrounded with difficulties, in proportion to the extent and variety of the observations which are requisite for forming scientific conclusions. If medical observers had been contented to look with simplicity into the series of events belonging to epidemic diseases, like Hippocrates and Sydenham, we should not have been so much in the dark at the present day. Facts apparently contradictory, at least as to the proper name and the contagious quality of certain epidemic diseases, such as the Levant plague, the Asiatic cholera, and the yellow fever, have been brought forward by men justly eminent in their profession, but wedded to particular opinions. Hence has arisen the extreme difficulty of knowing the truth. Physicians, on the very site of pestilence, have sometimes, like children at play, taken opposite sides, and maintained their ground with unseemly pertinacity; so that we may look in vain to either party for unprejudiced observations. The records of all modern visitations of pestilential epidemics present us with opinions and statements as much at variance as light and darkness; and hence we must conclude either that one set of observers are right and the other wrong, or both partially informed but blinded by prejudice, so that they cannot see any truth in their antagonists' assertions; consequently, that many things which they report as facts are only partial observations, or vague rumours, or hastily formed conjectures, or unconnected and adventitious appearances. Truth is sacred, and error cannot be propagated without some injury. How incumbent, then, is the duty of medical observers to inquire impartially and to report with fidelity! He that presents us with a physical observation clouded by his prejudices, on a subject so deeply important to the health and welfare of his fellow-creatures, is but a degree less culpable than the man who gives a false colouring to some moral or religious truth, which involves the dearest interests of humanity.

If this view be correct, where shall we look for the facts—strictly such—which may assist our reasonings on this weighty subject? It is not, clearly, to recorded observations of infection and of non-infection, adduced by contagionists and their opponents, that we must refer for those unexceptionable data on which some safe practical conclusions may be built. We may perhaps admit something from each, but must reasonably doubt their wholesale inferences.

The subject would be involved in a cloud of darkness which no diligent and honest inquiry could penetrate, if there were not other things besides facts of infection and non-infection—in short, other facts connected with the origin, spread, and decline of pestilential epidemics, (for to these we shall chiefly confine our attention in the present article)—which, though too much overlooked, throw a good deal of light upon the whole question, and not only point to something quite independent of their contagious and non-contagious nature, but help us to determine how much importance we should attach to these circumstances in the general estimate. It is fortunate for our science that there is such a class of facts, and that the lover of truth has not to range in a wilderness of uncertainty. It is also a source of gratification that many of these facts are admitted by both parties, or at least, with few exceptions, are not denied by either.

Now, the facts of a comprehensive nature above alluded to, which belong to pestilential epidemics, may be classed under the following heads; on each of which it is proposed to make a few general observations, with a view of drawing some conclusions from the whole.

1. The natural signs which are either the antecedent indications or the concomitants of a pestilential epidemic, such as intemperate seasons and unusual weather, deficient or unwholesome food, mortality among any species of the lower animals, uncommon abundance of some of the insect and reptile tribes, depopulation of birds, &c.

2. The singular changes which have been observed to occur in the common or reigning diseases of the place, before, during, and after an epidemic pestilence.

3. The changes in the symptoms, or type and character of the epidemic pestilence itself, and the circumstances attending its migrations from one place to another.

4. The facts relating to the connexion of epidemic pestilence with offensive cities, marshy grounds, and low filthy situations, bad food, and a condensed, filthy, and ill-fed population, in all countries; and, on the other hand, the exemption of those places where due attention has been given to cleanliness, wholesome and sufficient food, and a rational system of health police.

5. The facts given in evidence from quarantine establishments and lazarettos.

Before we proceed further, it is proper to explain what is meant by an epidemic pestilence: the term is used generically to include

several species. It denotes a destructive or fatal disease, which appears at uncertain periods or intervals, but at seasons of the year peculiar to different epidemics and to different countries, in large assemblages of human beings, already predisposed to receive it: it attacks its victims in succession with various degrees of violence, leaving however many untouched, during the course of a few weeks or months, in a particular place or city, and then declines by degrees, as it began, but with diminished force, either moving onwards to other places which it invades in the same manner, or entirely disappearing for the time.

The plague of Egypt and the Levant, the bilious fever of Spain, and the yellow fever of America, the cholera of India, and the low malignant fever of our own country, are different forms of pestilence, observed sometimes to prevail epidemically in their respective countries; for different countries seem to have their particular forms of epidemic pestilence, to which they are more liable than to others, and which, in common experience at least, do not invade each country indiscriminately. When individual cases of any of these forms of disease occur at unusual seasons, or at times when there is no tendency in the disease to spread; in other words, when there appears to be no predisposition in the population of any city or town to receive it, the disease is said to be sporadic or local: such cases may appear at any time in the country which gives birth to the disease. If such sporadic or local cases should by any chance appear in other countries, by whatever means occasioned or introduced, a multitude of facts seem to demonstrate that there is no danger of their spreading, at least to any alarming extent.

1. It is stated by Dr. Mead in his learned Treatise on the Plague* that a "corrupted state of air attends all plagues." Dr. Mead was an enlightened physician, and though his work was written professedly to establish the contagious nature of the disease, yet his researches into the histories of the various visitations of pestilence in different countries compelled him to admit that "a corrupted state of air is, without doubt, necessary to give the contagious atoms their full force." Dr. Russell, who practised at Aleppo during the plague of 1760-1-2, admits in its fullest extent the dogma of Mead, but expresses the fact in other terms, more philosophically perhaps; and denominates that state of air which is alone favourable to the propagation of disease, a *pestilential constitution of the air*; without which, he states, "it is incontestible that the plague will not become epidemical." It must not be forgotten that Dr. Russell was a warm advocate for the foreign origin of pestilential contagion; and that he maintained no combination of indigenous circumstances could give rise to the plague in Syria. Sydenham, also, who witnessed the rise of the plague in London in 1665, found it necessary to take a "pestilential

constitution of the air" for granted.* Here, then, is an ultimate fact, so far as the testimony of such eminent physicians can establish it—a principle on which to found an argument as clearly laid down as any other in natural history. We might not be disposed to contend either for the propriety of the terms used by Mead, or for the absolute correctness of those employed by Sydenham and Russell; but for a state of air, present or just past, and perhaps also of the body, indispensable to the epidemic rage of pestilential fever.

It is a fact too well known to be questioned, that plagues and pestilential fevers, whether the bilious yellow fever or malignant typhus, have often been preceded and accompanied by irregular and intemperate seasons; in other words, by great extremes in the weather. If we examine the histories of the plagues of London in 1625 and 1665, of the Netherlands in 1635-6, of Aleppo in 1740 and 1761, of Marseilles in 1720, and of Malta in 1813; if we turn our eyes to the modern visitations of pestilence in Spain and the United States, and the East Indies; or if we look back to the descriptions of the plagues of Athens and Rome, as recorded by Thucydides and Livy, without laying any stress on the poetical colouring of Homer, Lucretius, and Ovid, we find that some remarkable intemperature of the weather and seasons has been the antecedent, and, generally, a warm southerly constitution of the air a concomitant of these events. This intemperature, whether marked by excessive cold followed by excessive heat, or excessive rains followed by excessive drought, and *vice versa*, has so often concurred with fatal epidemical distempers to form one series of events, that we have the pestilential constitution, or *κατάστασις λοιμωδής* of the observing ancients, especially the Greek physicians, as clearly laid down as any aphorism in our science, and prognostics of pestilence framed accordingly. A volume might easily be filled with facts illustrative of this position; but we must premise one general remark, that, straitened as we are, by the nature of the work, within narrow limits, yet in so comprehensive an argument some general results must necessarily be assumed; pledging ourselves at the same time for the truth of the principle, whilst we are omitting the details on which it is founded.

There can be little difficulty in tracing a connection between intemperature of the seasons and famine or unwholesome food; and the relation of the latter to the production of epidemic pestilence is more clearly manifest when we consider that its violence almost invariably falls upon the poor. It is a remark of Dr. Mead, deduced from his previous enquiries, and confirmed by every pestilential epidemic subsequent to his time, "that it has never been known when the plague did not first begin among the poor." This observation is strengthened by the histories of the yellow fever in America and in the south of Spain, of the cho-

* Chap. i.

* Chap. ii. sect. ii.

lera in the east, and of our own epidemic fever, particularly in Ireland. The poor are the chief victims, because they are principally subjected to the exciting causes.*

Mortality among some tribes of the lower animals not unfrequently follows intemperance of the seasons. Sometimes this mortality is noticed among dogs, cats, horses, and mules; and sometimes among sheep and cattle used as the food of man. In the pestilence that raged at New Orleans in 1819, we are told that the cattle died:—"horses, oxen, and cows with rotten tongues; sheep and hogs with their hoofs dropping off, and calves with rotten ears." Dr. Hodges bears a very striking testimony to this fact in his *Loimologia*, or Account of the Plague in London in 1665:—"Many knowing persons," he observes, "ascribed the pestilence to the quantity of bad meat from the preceding sickness among the cattle, which was sold so cheap to the poor that they fed upon it even to gluttony." "It is incredible to think how it raged among them—to such a degree that it was called the *poor's plague*."

The question does not seem to have been entertained, whether the same physical causes which acted upon the cattle might not have acted also on that part of the human species which was most exposed to elemental vicissitudes.

Salvaresa supposes the epidemic fever of 1764, at Cadiz, was occasioned by the old and corrupted corn. "Amongst the poor," he says, "the disorder was most violent. In this year the animals were first affected; and the mortality was principally observed among birds that fed on grain, as pigeons, poultry, &c."†

In the fever of Cadiz of the year 1800, Sir James Fellowes asserts that "the air, from its stagnant state became so vitiated, that its noxious qualities affected even animals; canary-birds died with blood issuing from their bills; and in all the neighbouring towns which were afterwards infected, no sparrow ever appeared."‡

Dr. Mead states that "it has been observed in times of the plague that the country has been forsaken by the birds." This curious fact does not belong only to the form of pestilential fever called plague: it is one of the many phenomena which are scarcely reconcilable with the notion that gives to the causes of pestilence so confined a range as the intercourse with an infected individual or the exposure to fomites. Livy tells us that in the pestilence at Rome, A. U. C. 571, "not a vulture was to be seen for two years;" and Thucydides relates that in the plague of Athens "the birds that usually preyed on human flesh entirely disappeared." Diemerbroeck, the learned and candid author of the work on the plague of Nimeguen in 1636, records that "it often happened, when canary-birds died without any obvious cause in any house, the plague shewed itself

not long after in some of the family." He also states that birds were much more scarce than at other times:—"avium multo rarior numerus." It is mentioned by Dr. Short that "during the four months Dantzick was afflicted, in 1709, all kinds of birds, as swallows, crows, sparrows, &c. deserted the city."

"A *rubigo* or mildew, i. e. a dew impregnated with highly corrosive powers,* was anciently deemed one of the causes of epidemic diseases. The Romans, apprised of the pernicious effects of these mildews, instituted what they denominated *festa rubigalia*, and worshipped an imaginary God under the name of Robigo. Hoffmann mentions such a dew, 'ros valde corrosivus,' as having infested vegetables in 1693-4, whence the cattle died in multitudes.† And Ramazzini ascribes an epidemic to similar dews; at which time the vegetables, corn, and fruit became black, being affected with a 'lues rubigalis.' The same year was remarkable for the scarcity of honey; and most creatures that live upon what they extract from vegetables died or languished. Probably such occurrences led many of the ancient writers to mention the silence of the grasshopper, and the drooping inactivity of the bee and the silk-worm, among the presages of impending pestilence. As to the spots, which are said to have assumed various forms, especially those of *crucicula* or little crosses, and to have appeared suddenly on garments, utensils, &c. as they are recorded chiefly on the authority of monks, whose writings are highly tinged with superstition, they are scarcely worthy of serious consideration."‡

Most of the writers who treat of the prognostics of pestilence refer to swarms of some of the insect tribes. Lord Bacon particularly remarks that "those years have been noted for pestilential, wherein there were great numbers of frogs, flies, locusts, &c." The plagues of Dantzic, Nimeguen, and Marseilles, and many others, afford illustrations this fact. To give details of all the natural signs would not be compatible with our object.

2. To found a truth in science we must have recourse to general observations. Isolated facts are only valuable so far as they tend to establish general laws. There is no science in which what are called facts require to be viewed with more suspicion than in that of medicine; nor any department of it where there is more room for error than in that which comprehends the invisible region of contagious miasms and atmospheric impurities. We have the following general observation of Dr. Mead in relation to the matter before us: "Fevers of extraordinary malignity are the usual forerunners of plague, and the natural consequence of that ill state of air which attends all plagues." This admission cannot but be considered very important. It does not, however, depend upon the authority of Dr. Mead. The fact is confirmed by a most ample induction. Fevers of extraordinary ma-

‡ Rees' Cyclop. art. Epidemic.

lignity, and other forms of mortal disease, have been observed to be the usual forerunners of plague or epidemic pestilence in almost every country.*

It was rather triumphantly stated that the plague of Malta in 1813 formed an exception to this rule, in order to prove the position that the disease was imported from Alexandria; in fact, that no precursor fever ushered in that pestilence: and if we had no other accounts of it than those by Faulkner and Tully, we should have been left somewhat in the dark on this point. But the candid and enlightened Dr. Hennen informs us that "for four or five years preceding that in which the plague raged, sudden deaths were more frequent than ordinary, and during the twelve months immediately preceding, and especially for the last month of the period, the increase was still more remarkable, inasmuch as greatly to excite public observation."† "Apoplexies (or sudden deaths) and other diseases were never so general or so numerous in the memory of man."

"It is observable," says Dr. Heberden,‡ "that at its first breaking out the disease has never been known to be the plague. It has moreover very generally been preceded by a severe putrid fever." The plagues of Venice in 1576, of London in 1625 and 1665, of Nimeguen in 1636, of Naples in 1656, of Marseilles in 1720, of Aleppo in 1742 and 1760-3, of Holstein in 1764, and of Moscow in 1771, were all preceded by malignant fevers.

Now if any one should enquire what are the effects of that peculiar state of air which ushers in an epidemic pestilence, the answer attested by long experience is, the occurrence of malignant fever. This is one part of the history of such events. But let us notice more particularly the observation which Dr. Heberden has annexed to the statement of this fact, viz.: that "at its first breaking out, the disease has never been known to be the plague." The simple reason of this extraordinary circumstance, and of the doubts and dissensions which have sprung from it, is the gradual and imperceptible change of the malignant fever into the true pestilential fever or plague, and the contrariety of this fact to the medical systems and authorities which have assigned different forms of the same disease to different classes and orders in nosology. We may almost take shame to ourselves that we belong to a profession which, either from the imperfection of the science itself, or from the deficient observation of its followers, has exhibited so many instances within the last two centuries in different countries, of reproachful contention among the faculty, on the eve of pestilence, about its name and nature; and which hitherto has laid down so few solid data to secure practitioners from future quarrels on the same ground. Leaving

the disputes about contagion out of the question, the disputes about names or nosological terms have agitated physicians in Italy and France, and Russia and Germany, and Spain and America, not excepting our own country, till the sober and impartial members of the profession are mortified, and legislatures are wearied and disgusted; for the latter know not what is really matter of fact, and the former are unwilling to ally themselves with such fierce combatants. Lord Bacon's aphorism, in its general signification, has been repeatedly confirmed since his time, that "the lesser infections of small-pox, purple fever, agues, &c. in the preceding summer, and hovering all winter, do portend a great pestilence the summer following; for putrefaction rises not to its height at once." Lord Bacon was too much of a philosopher to intercept the regular series of natural phenomena by his own fancies, and too little of a systematic writer on medicine to perplex himself with the trammels of artificial distinctions imposed by names. But some physicians have endeavoured to show that there was only a casual connexion between the pestilential epidemic and the malignant fever, its forerunner; and numbers have on such occasions involved themselves in keen disputes, whether the name of malignant fever or that of plague was the proper appellation of the epidemic pestilence itself. In this way they have too generally trod the thorny ground of contention instead of the simple path of faithful observation; and the consequence is, that we have more of counter-statements than of unquestionable facts reported to us from the scene of every pestilential visitation.

Nevertheless, all is not confusion; and there are some things on which medical science may repose with satisfaction in reference to this part of the subject. Two important observations belong to it: the one is, that the malignant fever which precedes the plague, commonly reappears at its decline; and the other, that during the continuance of the epidemic pestilence itself, at least during its active prevalence, all other forms of epidemic disease, such as those which are peculiar to the place and to the season of the year, are entirely extinguished. With regard to the former, it may be noticed, that one of the first and most evident signs of the epidemic pestilence being about to cease its ravages, is the appearance of another form of epidemic fever, generally of that which preceded, and sometimes of a new train of diseases; this new order of things indicating that the pestilential constitution is changed, or, at least, the disposition in the air to foster and spread the principal disease, completely for the time removed. The second fact is interesting, both from the antiquity of the observation and from its accordance with modern experience; that, while the tyrant disease is prevailing, it usurps complete dominion, and suffers no other disease to appear of an epidemic character. This was noticed in the plague of Athens by Thucydides; and every pestilence since that memorable period has verified the observation. It was noticed particularly in the last plague

‡ See his observations above quoted: p. 85.

of Malta. A fact recorded by Sauvages* places this circumstance in a very strong light, viz. that when the plague was raging in the south of France in 1720-21, no greater number of persons died of the disease in the town of Alet—and none died of any other disease—during the year of its visitation, than used to be carried off by other diseases, though the plague absorbed all others, or in fact put them to flight while it was prevailing. This is an incontestible fact, and a sufficient answer to those who deny the operation of any general cause. For it is perfectly clear that if a vessel from Sidon brought the plague to Marseilles in 1720, as was alleged, and that the contagion was conveyed from thence to Alet in Languedoc in 1721, as was asserted, this accidental circumstance, upon that hypothesis, must have exerted a most extraordinary influence on the atmosphere of the town of Alet, or rather on the constitution of every one in it, if it put every other form of mortal disease to flight for a whole year after.

The general remarks above made, relative to the forerunners of plague and its insidious approaches and dominion over other diseases, apply also to the pestilential fever of Spain, and to the yellow fever of America. "The occurrences," says Dr. Halloran, "which preceded the epidemic of Barcelona in 1821, correspond with the old and recent observations on a similar subject in other countries; it almost invariably happening that the yellow fever of Spain is preceded by unusual diseases of various form and force, more particularly by bilious remittent fevers, which are often so aggravated and malignant that physicians themselves do not venture to define the line of demarcation between them and the avowed epidemic." In the "Sketches of the Medical Topography of the Mediterranean," by Dr. Hennen, who closed his professional career at Gibraltar in 1828, and who observed and wrote with equal candour and ability, we find it stated that, "in 1813 bad remittent fevers preceded the epidemic which raged at Gibraltar, and that its true nature was disguised, till it had made such progress as to be prevalent in every quarter of the town."

With regard to the transatlantic pestilence, Webster informs us that "the yellow fever never occurs in the temperate latitudes of America, except under a pestilential constitution of the air, manifested by other malignant diseases; and that it has been preceded by acute diseases, and followed by remittents, dysentery, and malignant pleurisy."

3. We believe that the remark of Sydenham applies to the plague, and the yellow fever, and the Indian cholera, and to every other form of epidemic pestilence; that "all epidemics at their first appearance seem to be of a more spirituous and subtile nature, in other words, more violent and acute, as far as can be judged from their symptoms, than when they become older."

These changes or varieties in an epidemic

pestilence, during a few months' career, might be considered at some length under three heads, viz. the proportional mortality, the appearance of the symptoms, and the alleged difference in the contagious properties; but a very brief notice of each must suffice.

As to the first, it appears to be a universal fact, that at the first rise of an epidemic pestilence, the proportional mortality is always greatest; and, on the contrary, at the decline, whether a few months or weeks only comprise the whole career, the disease loses much of its fatal character; putting entirely out of view the interference of medical art in either case. Knowing this to be the law, though we might not be surprised that, at the appearance of a new and formidable disease, when all is perplexity and alarm, medical men should be at a loss respecting the proper treatment, and should often witness the unequal conflict of their science; yet we can scarcely withhold a smile, when we see so much self-congratulation, and the numerous cases of recovery at the decline attributed to some improved plan of treatment.

With regard to the symptoms or outward character of an epidemic pestilence, we believe the assertion may be safely warranted, that it has never happened that the appearances were uniform in its beginning, height, and decline. As to the plague, this is well known to be the case: Sydenham, Russell, and others, note the fact. On the points of distinction between the varieties of the disorder we need not dwell; though it would be a work of no small practical utility to consider the usual periods in which the bubo, carbuncle, purple spots, and milder features of the disease make their appearance. But if our limits allowed, it might be shewn that even the quick or apoplectic nature of the attacks at the commencement, bears a near affinity to some of those precursor diseases, which, in London, Marseilles, Aleppo, and Malta, ushered in the pestilence itself; and at the decline the mild features and diminished mortality exhibit a striking contrast with its previous violence and malignity. It would scarcely be right to conclude this part of the subject without noticing an observation of Sir James M'Grigor, shewing the varieties which the same disease will sometimes assume under the influence of different localities and seasons. "When the plague first broke out in the Indian army in Egypt, the cases sent from the crowded hospitals of the sixty-first and eighty-eighth regiments, were from the commencement attended with the typhoid or low symptoms. Those which were sent from the Bengal battalion, when the army was encamped near the marsh of El-Hammed, were all of the intermittent and remittent type. The cases which occurred in the cold rainy months of December and January had much of the inflammatory diathesis; and in the end of the season, at Cairo, Ghiza, Boulac, and on crossing the isthmus of Suez, the disease wore the form of a mild continued fever."

With regard to the appearances of the yellow fever in Philadelphia in 1793, Dr. Rush tells

* Nosol. Method. vol. i. p. 415.

us, that "the frequent absence of a yellow colour led to mistakes which cost the city several hundred lives;" as the want of inguinal tumours at the rise of the plague of Messina in 1743, caused thirty-three physicians out of thirty-four to deny the pestilential nature of the disorder, and to neglect the proper means of checking it, till it was too late.

It might appear that we were departing from the rule at first laid down, and entering upon disputable ground by taking any notice of contagion; but the observations to be made being formed by decided advocates of that doctrine, they ought at least to merit due attention from all who do not deny it, especially from those who ascribe so much more to contagion than to atmospheric influence. Dr. Russell informs us that at the beginning of an epidemic plague the contagion is so feeble, in other words, so many of the attendants escape infection, and such long intervals occur between the cases, as to cause serious perplexity respecting the nature of the disorder;* and that the contagious property is nearly, if not quite extinguished, at the decline, both in persons and clothes, must be obvious to every unbiassed observer who considers the facts; for the disease has never ceased in any place for want of subjects to act upon.† And the comprehensive remark of Dr. Russell is a striking answer to those who can trace the extinction of an epidemic plague to no other means than police regulations. It is in these words: "From what has been said of London, Aleppo, and Marseilles, it would seem as if there was little observable difference in the mode of its termination, in cities where purification was practiced and where it was not."

In all stages of the bilious pestilence of America its contagious property is so indistinctly marked, that Dr. Rush felt himself obliged to confess that "the interests of humanity were deeply concerned in the admission of the *rare and feeble* contagion of the yellow fever." And although contagion is what popular opinion fixes upon the plague as its necessary attribute, yet there cannot be a shadow of doubt, that at all times this contagious property of the disease depends on so many contingencies to give it force, as to justify the remark of Dr. Russell, "that the dread of contagion from plague may, consistently with truth, be moderated."

Dr. Russell sums up the matter in these words, after stating that "the constitution of the air is the cause which heightens or lessens the susceptibility of the contagion."—"1st. In the beginning of a pestilence the disease, though less contagious, appears in its most fatal form. 2d. On its increase and height, though manifestly more infectious, the malignity of the effluvia does not seem to be exacerbated, because milder forms of the disease are then more common. 3d. Several persons infected from the same subject are variously afflicted; some in a greater, some in a lesser

degree, the disease being modified by difference in constitution. And, lastly, persons in constant communication with the sick, who have resisted infection in the most contagious stages of a pestilence, are sometimes attacked in its declining state; which seems to indicate some change in the habit of the individual, not the increased activity of the contagious effluvia."*

"At Aleppo there were instances of persons who had exposed themselves two or three successive seasons, being attacked at length when the contagion was fast on the decline, and the distemper had become in all respects milder."†

In considering the progress of an epidemic pestilence from one country or city to another, it must be viewed as a remarkable fact, that a disease which has become so mild as to lose the power of doing mischief in one place, when transferred to another should begin in the same insidious and destructive manner, and continue to rage with the same violence, and at last moderate its fury in the same way as it was observed to do in the former; making due allowance for the variety of circumstances which must tend to modify the effects in different places. On the common exemption of strangers and others we have not time or space to enlarge.

4. The evidence which bears upon the connexion of pestilence with filth, &c. is remarkable: it is both negative and positive. The negative is the absence of pestilence from those cities of Europe, now for more than a century and a half, which have adopted a system of health-police, not by guarding against foreign contagion, but by domestic cleanliness. The positive is the devastation of those where attention has not been paid to these points; and the immediate good effects which have resulted from sanatory regulations wherever they have been adopted. "Dr. Heberden," as was observed by Bateman in an able article on the subject, "has collected the most ample and satisfactory evidence of the connexion of plague and of the malignant contagious fever, which usually precedes and accompanies it, (if, indeed, they be not modifications of one and the same disease,) with the filth of crowded, ill-constructed large cities, in all ages and countries." London, Paris, and the cities of the Netherlands, which were formerly scourged by pestilence, whenever untoward causes operated, such as wars, uncultivated fields, famine, or unwholesome food, wretchedness occurring in a congregated mass of human beings, added to irregular seasons and intemperature of the climate, have been comparatively exempt from its visitations since their streets were paved and widened, and kept clean from animal and vegetable filth, which formerly lay in heaps under a scorching sun; since sewers have been dug, and fresh water has been abundantly supplied to them; since houses have been better ventilated, and built more for the purposes of health than of harbouring the greatest mass of people in the smallest possible space; and

* Russell on the Plague, pp. 19 and 261.

† Researches, p. 156.

* Treatise on the Plague, p. 261.

† Ibid. p. 301.

since all kinds of stagnant pools have been removed from their vicinity. And, besides the exemption from pestilence, the type and character of the reigning diseases in some of these cities have been much changed for the better; and the relative mortality has been wonderfully diminished. This is strikingly exemplified in London.

But as it was always in the most filthy parts of those cities that plague "originated and maintained its head-quarters," so, in other cities, which have been tardy in adopting such improvements, as Marseilles, Moscow, and other places, there was a corresponding liability to its invasion much later than the period above noticed. And now, if we turn our attention to the domestic sources of malignant fever still subsisting in the cities of Spain, which have so often been scourged with it of late years; or to the present state of Constantinople, Cairo, and Alexandria, we need not wonder at the facts which experience has thus unfolded to us from time to time in confirmation of these principles. "All the towns and cities (in Spain) which suffered from the yellow fever were, with the exception of Cadiz, filthy in the extreme, disgustingly so, and very objectionable on the score of ventilation, situation, and form of construction: while the different towns of Arens, Matero, Badalona, Tarragona, Vimaros, Benicarla, Valencia, Alcama, Velez, Malaga, Maraballa, Estepona, Vejer, Conil, Puerto Real, Rota Chipiona, Orcos, and Medina Sidonia, all of which are in the vicinity of the sea, and which, it may be presumed, from their relative situations, communicate freely with the theatres of disease, were not affected by the malady. They seldom, indeed, suffered in any other years; because, independent of their localities being better chosen for health, they are comparatively clean."*

In the cities of the east which are still scourged with the plague, they nourish from year to year the seeds of the disorder in their own bosoms, in climates, too, the most favourable to the propagation of pestilential epidemics; yet in these very places it is only in seasons when aggravated causes have been operating, that pestilence in an epidemic form appears; and when it does shew itself, the phenomena of its beginning, and height, and decline, correspond with those which have been stated to occur in other places, allowing for the difference of climate. Sir John Webb notes the common epidemic, or rather endemic, prevalence of plague in Egypt in these words: and the reader is requested to bear in mind the difference in the violence and symptoms of the disease in its beginning and decline. "The course of the disease is nearly the same every year, and equally varies in different seasons of the year. In Egypt it commences in November, at which time it rages with its most deadly malignity; and those who are affected by it sink into the grave almost without complaint. It continues its ravages with little abatement through the winter and the earlier

part of the spring, when, as the weather becomes warmer by the approach of summer, its attacks are less frequent, its symptoms much milder, and it subsides into a manageable malady." Pappou, a late French writer, tells us, that even in Egypt, when it was formerly well cultivated, the climate was healthy compared with that of Rome in its decline.

With regard to the indigenous causes adequate to the production of yellow fever or the transatlantic plague, which Dr. Rush had frequently an opportunity of observing, he states, "Philadelphia must admit the unwelcome truth sooner or later, that the yellow fever is engendered in her own bowels; or she must renounce her character for knowledge and policy, and perhaps with it her existence as a commercial city."

Although extensive marshes give rise to diseases of a febrile character every year among those residing in their vicinity, yet it is often found that, in seasons of uncommon intemperature, the malignity and fatality of such diseases are much increased. And this cause, concurring with other circumstances, has frequently produced a destructive pestilence.

Diodorus attributes a pestilential disease which occurred among the Carthaginians at the siege of Syracuse to the following combination of circumstances:—"the multitude of people confined within a narrow compass, the situation of the camp in a low and wet ground, and the scorching heats in the middle of the day, succeeded by cold and damp air from the marshes in the night." Fracastorius ascribes a malignant epidemic fever in Italy, in the sixteenth century, to an extraordinary inundation of the Po, which, happening in the spring, left marshes, and those corrupting infected the air through the summer. Forestus remarks that from the putrefaction of the water only, the city of Delft, where he practised, was scarcely ten years free from the plague or some pestilential distemper.* "At this day, says Assalini, the lakes, the marshes, and the filthiness which one finds in the cities of Lower Egypt, are the principal causes of the frequent diseases to which they are subject, and which can never be eradicated until we have found means to purify the atmosphere of their environs. This important advantage may be obtained by draining off the water of the lakes, and filling them up; by keeping the cities clean, paving them, and giving a free exit to the rain water, which stagnating in different parts of these cities, becomes corrupted, and, conjoined with filth, infects the atmosphere. By similar operations several cities and provinces in Europe, America, and the Indies, have been rendered healthy. The inhabitants of the citadel of Cairo, which is favourably situated on an eminence, during the plague of 1791 were exempt from the disease, which laid waste the lower town; with which, nevertheless, they continued to hold constant intercourse."

Bombay has been rendered much more healthy than it was formerly, by a wall built to

* Good's Study of Medicine, vol. ii. p. 81.

* Rees' Cyclop. Art. Epid. Dis.

shut out the sea, which formed a salt marsh, and by an order that none of the natives should manure their cocoa-nut trees with putrid fish.* According to Diogenes Laertius, Empedocles, the Sicilian philosopher, removed pestilential diseases from the Salenuntians, by conveying two streams of running water into the stagnating river round their city which gave rise to them.† Modena was subject to malignant fevers from a like cause; and by filling up the ditches and morasses which surround the citadel, these fevers have almost disappeared.‡

5. It is a singular illustration of the preceding views, that in none of the quarantine establishments on the continent, and in none of the stations appointed for the purpose in the British islands, along so great an extent of coast, engaged in such universal commerce, and for such a number of years, has there ever been an instance of a person suffering death in the process of expurgation or purification of goods imported from countries afflicted with pestilence. Evidence to this effect, so far as it relates to our own shores, was laid before a select committee of the House of Commons in 1819.§

Professor Assalini, who has given us some interesting particulars concerning the plague of Egypt, communicates the result of his inquiries respecting the matter in question in these words. "It has often been said, that in breaking open a letter, or in opening a bale of cotton containing the germ of the plague, men have been struck down and killed by the pestilential vapour. I have never been able to meet with a single eye-witness of this fact, notwithstanding the inquiries which I have made in the lazaretto of Marseilles, of Toulon, of Genoa, Spezia, Leghorn, Malta, and in the Levant. All agree in repeating that they have heard of such an occurrence, but that they have never seen it happen. Citizen Martin, captain of the lazaretto at Marseilles, who for thirty years has held that situation, told me that during that time he had seen opened and emptied some millions of bales of cotton, silk, furs, feathers, and other goods coming from several places where the plague raged, without having ever seen a single accident of the kind." The chief physician of the lazaretto at Malta informed Dr. Maclean that during the period of fifteen years in which he frequented the lazaretto, no cargo arrived, the expurgation of which infected a single individual in the establishment; and according to the testimony of the deputy-inspector Grieves, none of the persons so employed were affected in that island during the plague of 1813.

If we go to the Levant, we have the evidence of Sir James Porter, that "all sorts of merchandise susceptible of infection pass through the hands of our English factors at Aleppo, Smyrna, or the places from whence they are

shipped; they are examined strictly by them or by their servants; and there is not upon record, nor has a single living witness ever related an instance of an English factor or servant's dying of the plague, at any of the sea-port towns, or in any other part of Syria or Asia Minor, and but one only in Constantinople, in almost a century; though the disease very frequently rages in that metropolis."**

In connecting together the preceding classes of facts and observations, it is necessary to premise that a mere sketch is only given, and very general conclusions only can be drawn; but we believe that no theory of epidemic diseases will be perfect which does not include a comprehensive survey of all these circumstances.

As to the phenomena of the weather and seasons, it must be allowed that the physical signs deduced from their intemperature and irregularities, such as blights, mildew, abundance of insects and reptiles, flight and death of birds, murrain among cattle, and pestilence among brutes, are uncertain in their development in different countries, and even in the same; and that some pestilential visitations have occurred without any very striking signs of this sort having been noticed. But though this may have been the case, it does not appear that extremes of some sort have ever been wanting in the air and seasons as accessories to the cause. The uncertainty, however, in regard to the outward visible signs of atmospheric impurity, as recognized in the *manifest* qualities of the air, has induced some philosophers to suppose that there were *latent* qualities which neither our senses nor chemical knowledge could detect, implicated in the causes of the mischief. Some, accordingly, have given reins to their fancy, if they have not also given occasion to the advocates of contagion to confirm their exclusive opinions, in seeking for the cause of epidemic pestilence in mineral exhalations from the bowels of the earth, emitted by volcanos, earthquakes, and such-like convulsions. But though we may have some persons admitting a corruption of the air by mineral vapours, and others a contagious seminum as being necessary to the effect; yet a corrupt air which cannot be detected, and a contagious principle which must be hunted for in a variety of channels, and is constantly eluding the search, may still leave the truth in as much obscurity as it was before. We are therefore compelled to leave such unsubstantial hypotheses, for they only remove the difficulty a step. The notion of Sydenham, however, "that epidemic diseases arise from mineral vapours from the inmost bowels of the earth," comes somewhat nearer the truth, if we connect it with the effluvia and the effects of local filth and of animal and vegetable impurities in large ill-constructed cities and marshy situations. In situations of this sort vapours do indeed, at times, rise from the earth, (if not mineral impregnations,) which are known to be highly destructive. Yet, on the other hand, if local causes like these are existing year after year, and a general pesti-

§ Researches into the Laws of Pestilence, by T. Hancock, M.D. p. 233.

* Russell on the Plague, p. 309.

lence is but rare, how are these to be considered the cause? It cannot be doubted that local filth alone will not explain the circumstance. Like atmospheric intemperature it may contribute something, but it is not the cause. If, however, we add to the effects of unseasonable weather and of corrupting animal and vegetable materials, those of deficient or unwholesome food, and congregate the poor victims together in close sordid dwellings; surrounded and contaminated by local filth, then we fill up the range of predisposing causes which prepare the debilitated bodies of the wretched poor for the sudden invasion of acute disease, and lay them prostrate before the sweep of pestilence. But of famine, or unwholesome food alone, it may of truth be predicated, as of other individual causes, that it will not produce a pestilence. So that neither irregular seasons and bad weather alone, nor the effluvia from putrifying animal and vegetable substances alone, nor vitiated bodily secretions, however concentrated, alone, nor even diseased human secretions, the product of fever, however aggravated, alone, whatever marvellous stories may be attached by different authors to any of these particular circumstances, will ever be likely to produce a general pestilence. This opinion is hazarded, not without being duly weighed, after a careful enquiry into the specific effects of these several causes, viz.: atmospheric vicissitudes; animal and vegetable putrefaction; malaria, whether from marshes or the mouths of great rivers, or cities or camps; famine or bad food; and the concentrated poison of human filth and human disease. Yet the writer of this article is not the less assured that all these causes together have a powerful combined influence in occasioning that predisposition of body without which no epidemic plague will make any progress; without which no contagion will spread; and which, if in some few cases it require the assistance of a contagious principle to produce the disease in time of pestilence, yet in the majority of instances appears to surrender the multitude a prey to the common enemy without the medium of contagious intercourse. Nor is it, on the other hand, to be doubted that fear, wretchedness, fatigue, and excess, with other debilitating powers, both in an epidemic season and at other times, may co-operate with some of the predisposing causes above mentioned; and, perhaps, with contagion, to produce the disease even in the bodies of those who, living in the comforts of life, have been subjected neither to the undermining effects of bad food, nor to the corrupting influence of a vitiated air and local filth. It is probable that a predisposition is formed, occasionally, to take the disease in this way; but that it is very rare, and never has been the cause of general pestilence.

As far as facts therefore enable us to form any general conclusions in regard to the circumstances which conspire to produce a pestilence, the following appear to be legitimate deductions, without having recourse to the obscure notion of a pestilential constitution of the air, except in so far as we may apprehend it as an

ultimate fact. For it is in vain to inquire into the subordinate reasons, why an epidemic pestilence, in obedience to the laws of this constitution of the air, either observes certain seasons of the year, or a limited number of weeks or months to run its course, or a progressive movement in families and neighbourhoods, and cities and countries.

1. Intemperature of the air, or a series of unusual and irregular weather, lays the foundation for acute diseases in a congregated mass of human beings.

2. Deficient or unwholesome food predisposes the bodies of the poor, especially, to be acted upon by this intemperature.

3. Local impurities, composed of effluvia from putrefying substances, in the vicinity of marshy situations or of large filthy cities, in proportion to their extent and to the concentration and virulence of the miasmata, aggravate the preceding causes by a partial pollution of the air.

4. Human secretions and excretions, hurtful in this state of the body even without actual disease, but become virulent by accumulation, and poisonous when subjected to fever, acquire a degree of malignity which is proportioned to the congregated mass.

Hence, if the air, and the soil, and the food, and the state of the animal secretions contribute each a part to the production of a pestilential fever, it cannot be said that the cause resides wholly in any one of them. From the combined effects of all, however, a predisposition is formed which makes some inhabitants of a town or city liable to pestilence sooner than others, some towns or cities sooner than others, some nations sooner than others, in proportion as they have been subjected to the causes before mentioned. If so many causes did not successively concur to this effect, pestilence would be much more common than it fortunately is. We do not depend, therefore, upon the casualties of arresting contagious intercourse, or of expurgating imported *fomites*, but upon the rare concurrence of the several subordinate causes, for our exemption.

And if the prudent adoption of some salutary regulations should prove availing, even in the very time of a pestilential visitation, to lessen the mortality and to mitigate the disease, as they have been often found to do, much more should such measures prove availing, as preventives, when practically adopted in any city, as the constant and habitual means of preservation.

Now, unquestionably, the removal from close and filthy habitations and a vitiated neighbourhood to a pure air, if such can be found; and the separation from each other, and dispersion over a large space of healthy ground, of the distressed multitudes who are thus predisposed, and the supply of sufficient and wholesome food to them; and cleanliness in their persons, clothes, and apartments; have been fully ascertained to be the best prophylactics, even in time of pestilence, which human skill can devise, and the surest means of arresting this formidable evil. The citizens of the United States

know well what security lies in these means : the principles are not visionary. And here we must protest against the unscientific attempt to establish a specific difference between the Levant plague and the yellow fever, as to the former possessing a contagious property, and the latter none. It is astonishing that a physician with a mind so energetic as Dr. Bancroft possessed, should have wasted his strength with so much pertinacity in that ineffectual labour. Too much stress has without question been laid upon contagion in both diseases. To take this quality, which is only incidental, from one of these diseases, in order to give it to the other in excess, when it is known that some deny it even to the latter, is not the way to advance our knowledge of this subject. But it might appear invidious to place in contrast with means of preservation and precaution like those just mentioned, the modern European policy of keeping our fellow-creatures, when threatened or afflicted with pestilence, shut up in the hot-bed of disease ; the sick and the healthy within files of bayonets, or in the hold of a vessel with a crowded and exhausted crew. Precautions like these, though in good truth their necessity is much to be doubted, we may not call barbarous and unenlightened, if they be sanctioned by a British senate, nor inhuman, though practised by Christian governments of the nineteenth century, in direct opposition to the benevolent usages of Greeks and Romans, and even modern Pagans ! But we do call barbarous, and unenlightened, and inhuman, the conduct of those members of our own profession at Noya, who, through fear of the contagion, "carried a spear in their hands for the purpose of killing any patient (and the case really happened) who in a fit of delirium might attempt to seize the physician or attendants."* Our abhorrence of such cowardice and cruelty is scarcely to be expressed in any temperate form of words. No reasonable man can doubt that the sacrifice of human life from the unwarranted, and, in its effects, unfeeling dread of contagion, operating as it does throughout all its details of practical application from year to year, is and has been enormous.

But, on the other hand, to maintain that indiscriminate intercourse may be allowed between the sick and the predisposed in their impure dwellings, and that human beings may be cooped up together, in plague or yellow fever, or Indian cholera, or malignant typhus, or dysentery, without adding either to their own danger, or to that of their attendants, is to take that ultra view which is opposed to the experience of all ages. We do not want nice distinctions about a contagious and infectious atmosphere for practical purposes : they are terms which give occasion to many words and to little practical good. The effects of each have been overstated, and of none more than of contagion, when viewed apart from other circumstances. Contagion of any disease can do but little harm at any time, in any country,

unless there be a strong predisposition of body concurring with a pestilential season. The signs or indications of this pestilential season, and the way to remove this predisposition, are of far more consequence than the precaution against a foreign contagion. Judicious and moderate physicians are more and more tending to this view of the subject.

Contagion is not a necessary incident of any disease ; but some look upon it as constituting the very essence. A few brief remarks on this subject may perhaps be suitable in this place. The public are wearied with statements from medical men, that such and such diseases, of an epidemic nature, are contagious, and that they are not contagious. They may well wonder at the imperfect state of a science which has not yet settled points of so much importance. What are thinking men to conclude when they see medical authorities thus opposed to each other ?—either that the opinion of the most eminent physicians is good for nothing, or that both parties are right—in fact, that under peculiar circumstances, these diseases are sometimes contagious and sometimes not. But it is a great misfortune that partial observers allow their minds to be tintured with exclusive opinions, of which they become as tenacious as if these opinions could be verified by an undoubted demonstration. The consequence is, that little weight attaches to either side. It is too much the habit of all persons to look at pestilential fevers of every kind, as if contagion was the quality which peculiarly characterised them. But a very simple view of the case should convince any one that the animal effluvia, or morbid secretion from a diseased body, which constitutes contagion, is not necessarily a poison to all who come within its influence. Small-pox contagion itself is inoffensive to thousands. In those who have had the disease the predisposition is destroyed. There must be a strong predisposition of body to receive the contagion of any other disease ; and this strong predisposition is what lays the multitude prostrate before an epidemic pestilence : so that, in some cases, an intense dose of the poison ; in others, its protracted application ; in others, an exhausted state of the body from defective nourishment ; in others, extreme fatigue and watching ; with mental depression ; in others, the debility which follows a debauch ; proves, one or the other, to be the exciting cause which brings this predisposition into action while the epidemic constitution, whether this depends on the air, or the body, or the season, is prevailing. It is no fanciful idea that an epidemic constitution is thus limited ; for how otherwise could it happen that cholera, like influenza, requires but six or eight weeks to run its course, to become, in fact, mild and impotent, after it has raged with fury ; while the Levant plague and the bilious pestilence or yellow fever take up three or four months ? If cholera halts days between the first few cases, pestilential fever halts weeks. Cholera observes precisely the same law as pestilential fever, when epidemic : it is violent and fatal at the beginning, mild and harmless at the de-

* Quarterly Journal of Foreign Medicine, No. 5, page 7.

cline; and, if its contagious nature were as well marked as that of plague, we should have the not less remarkable fact, that when it was most violent, and acute, and fatal, it was least contagious, except at the decline, when, as in the plague, contagion is extinct.

The preceding remarks have occurred in relation to the predisposing causes of pestilential diseases, which, perhaps, in most cases, go nine-tenths of the way in producing an attack of the disease, or only wait for some exciting cause while the body is already on the verge of pestilence. It remains to offer a few observations on the precursor diseases.

That no pestilence comes alone, or without some heralds of its approach, seems to be a truth fully established in the unvarnished history of every such event. In most places it is the crisis of a series of fatal and uncommon diseases. The forerunner of plague is usually a malignant fever—of yellow fever, a fatal remittent; which often appear again at the decline. The difficulty of distinguishing between this malignant fever and the pestilence itself has never failed to excite dissension among the faculty, both as to the name of the disease and as to its contagious property. These disputes belong essentially to the present state of opinion on this most important subject; and until correct views prevail over Europe, there will not be a pestilential visitation without them. We can easily account for this difficulty; for what nature has joined, both in series and affinity, man has attempted to disjoin. Physicians, therefore, have perplexed themselves with the most unaccountable dilemma that ever found its way into any science. They have acknowledged a disease called malignant fever, which has ushered in an epidemic pestilence, *to be their own*, or at least the product of the country where it appeared; but as soon as a little change in its character has taken place—which amounts to nothing more than a change in degree, not nearly so great as that which takes place in the pestilence itself, in the short course of its career—which change in a few months is put off again, *then* it is to be accounted of foreign origin, and ships and goods are condemned as the supposed channels of introduction; or it is well if even human life, as has often been the case, does not pay the penalty. The word contagion, with the fears attached to it, has been suffered to preoccupy the minds of statesmen and of many eminent practitioners to such a degree as to destroy all scientific research, to send them hunting after an *ignis fatuus*, which never yet was found, and to cause them to neglect those wholesome internal regulations which, if well observed, might bid defiance to all foreign contagions, supersede quarantine, and in great measure relieve commerce from its present injurious restraints.

With respect to that law of pestilence above alluded to, according to which other forms of acute disease are banished while the epidemic pestilence continues to prevail, it is absolutely incredible, or at least inexplicable on any sound principles, that one epidemic disease—whether plague, or bilious pes-

tilence, or yellow fever, or cholera—which banishes a whole host of other epidemic diseases from any country while it is raging, and then suffers them to start up when it is about to disappear, should owe its origin to any other place than to that country. It is quite incredible that the fortuitous importation of a foreign contagion should so entirely change the atmosphere of a country, on which its minor epidemics manifestly depend, as to drive them away in this manner, in order that it may exercise the power of destroying alone, until it shall withdraw itself to act the same tragedy in some other place; not only so, but that the presence of this foreign disease should restrain for the time the operation of the ordinary causes of mortality from the common acute and chronic diseases to which the inhabitants are liable, which is known to be in great measure the case during the rage of an epidemic pestilence.

We might also lay some stress upon the fact that, with singular power of selection, an epidemic pestilence chooses its own season of the year, from which it is observed to vary but little in the same country or climate, both to begin and to conclude its ravages.

If, in addition to these things, we consider the epidemic pestilence itself, and its varying features and character in its short career, we can arrive at no other reasonable conclusion than that it originates entirely where it rages. We have seen that no pestilential epidemic is one form of disease, of unvarying type and destructive power, from the beginning to the conclusion; nor, by the admission of the great advocates of contagion themselves, of equal contagious property in its different stages, if indeed it be possible to ascertain this point, which is a question; and the question hinges upon the very slight degree of contagious property manifested at the commencement, when the disease is most malignant and most fatal, as well as upon the acknowledged extinction of contagious property at the decline.

By these facts we are compelled to admit that such a change takes place in the air, or in the state of the miasmata from the soil, or in the human body, perhaps in all together—a change so extraordinary as to alter the type and character of a pestilential disease from a fierce to a mild state, and to expel it entirely, destroying every vestige of contagious property in it; but according to the doctrine of imported contagion, we must not admit that any combination of indigenous causes can produce it.

We are called upon by the facts to admit that the precursor malignant fever, which is so nearly allied to plague that the most sagacious physicians have allowed their inability to distinguish them, is an indigenous disease; but, in condescension to common opinion, we must persuade ourselves that the disease which expels this native malignant fever, and that only for a time, is *foreign*! It is marvellous that men of science could ever have been influenced to lend their sanction to such incongruous notions. But, in truth, the difficulty

of ascertaining the real facts has been the cause of much erroneous opinion.

Upon principles which allow of the domestic origin of pestilence, we can more easily explain the singular facts so frequently recorded in the annals of epidemic diseases, relative to the exemption of foreigners, as well as of the inhabitants of other cities, in a place visited with pestilence. Many facts seem to indicate that it is not the *immediate* state of things only which is to be taken into account, in order to explain the true causes of pestilence; but that the undermining effects of some remote causes, which have been some time in secret operation in certain communities, ought also to be considered; for it is abundantly proved that a peculiar constitution of the air, on which the progress of pestilence in part depends, will not of itself induce the disease in strangers even holding intercourse with the sick inhabitants, without a fit habit of body to receive it. And, on principles like these, we can account for the escape of such inhabitants of the place as are living in clean secluded situations, enjoying all the necessities of life, and but little exposed to the exciting causes—as in well regulated hospitals and abbeys—far more satisfactorily than on the supposition that they have been guarded from the contagion.

It is scarcely necessary to recapitulate the facts illustrative of the same views, and establishing the same principles, which belong to the exemption of those cities from the ravages of pestilence, where the wise regulations of cleanliness and attention to the poor have been adopted; and, conversely, the continuing liability of those in which these wholesome rules are neglected.

If we wanted evidence of every other kind, the testimonies of those who have superintended lazarettos and quarantine stations, furnish an argument of no small weight against the doctrine of imported febrile contagion having in any case been a cause of general pestilence; for the confused and contradictory accounts of the supposed channels by which contagion has been alleged to be conveyed into different countries, of which many examples could easily be furnished, might of themselves occasion serious doubts upon the subject.

In conclusion, the separate points of evidence, added together and weighed impartially, constitute a theory or system of connected observations and dependent results, tending remarkably to establish the opinion, with as much certainty as the case will admit, that the whole apparatus of an epidemic pestilence, from beginning to end, is the production of the country where it rages.

(T. Hancock.)

EPILEPSY.—Every one is aware of the difficulties with which the consideration of this disease is encompassed, especially with regard to its etiology—difficulties which we have no expectation of removing; nor can we hope materially to add to the information which is already before the public relative to the method of treating epilepsy; but we are willing to put

our mite into this treasury of medical lore: and being persuaded that those who are afflicted with epilepsy may often be made less wretched by rendering its paroxysms less frequent, even when the patient cannot be perfectly cured, we willingly avail ourselves of the present opportunity of urging physicians to re-consider this disease with care, and no longer, as many of their brethren have done, to pronounce epilepsy, when unaccompanied with deformity of the cranium or imbecility of mind, incurable, until, first, they shall have endeavoured to correct in the patient every function which is disordered, and until, secondly, they shall have exhausted the whole armoury of the empiric.

Indeed, it would seem that all those diseases which have been termed *opprobria medicinæ* ought to be revised with care, were it only to seek for new and more effectual palliatives. Every year, by the industry and ingenuity of the naturalist, the chemist, and the mechanist, new agents or more refined expedients are discovered for abating the discomforts caused by infirmity and pain; and nothing is more commendable in a physician than being familiar with all those resources of art by which incurable diseases can be alleviated. The euthanasia is a subject worthy of increased attention. The name of Ferriar, who wrote a paper on the treatment of the dying, ought never to be mentioned without an honourable addition, on account of the humanity which guided his pen upon that occasion.

There exists yet another reason why epilepsy should be investigated with renewed attention. This disease has often brought candor and cunning, science and ignorance, into conflict: in the treatment of epilepsy the empiric, ignorant and bold, and often confident in proportion to his ignorance, is, in the estimation of the world, superior to the physician who is influenced by true principles of science and morality. The physician ought to use all proper means of preserving epileptics from falling into the hands of the designing, whose nets are ever extended to catch the unwary. He ought to avail himself not merely of science and observation, of the advantage which he obtains from being enabled to prognosticate where an ignorant person can only guess, but also of prudent reserve, time, and favourable contingencies;* and he ought not to forget that epilepsy will often spontaneously terminate, which favourable termination nine-tenths of the community, educated and uneducated, patients and their friends, in spite of a disclaimer on his part, will attribute to the last medicine

* The following are instances of these contingencies. Puer decem annorum, jam a tribus annis epilepticus, frustra adhibitis multis remediis, corripitur febre epidemica, pluribus molestis symptomatibus stipata, et feliciter superat hunc morbum, et postea ab epilepsia immunis manet. Miscell. Cur. Dec. iii. Ann 7 and 8, p. 2:8. Fuere quibus excitatus morbus, et nutritus, opipara ac desidiosa vita, subita fortunarum jactura per omnem vitam, haud contemnenda plane compensacione, siluerit. De Haen, pars v. Rationis Med. cap. v.

prescribed, according to that established aphorism of popular wisdom, *post hoc ergo propter hoc*.

Epilepsy, ἐπιληψία, (from ἐπὶ and λαμβάνειν), so termed from the suddenness of the seizure.

Synonyms. *Morbus divinus*, *M. herculeus*, *M. sacer*, *M. comitialis*, *M. caducus*, falling sickness, *mal caduc*, &c. Many of these appellations prove the dismay with which the spectator is affected upon witnessing this frightful disease. When a person, with whom, perhaps, one was engaged in agreeable conversation, and who apparently was in perfect health, suddenly losing all sense, is thrown down and reduced in appearance to a state of hopeless agony, it is not wonderful that, in the days of ignorance, general amazement should have been the consequence; nor that, during the reign of superstition, the frightful scream and struggle of epilepsy should seem to argue the interposition of an offended deity, in this emphatic manner testifying disapprobation of passing events. Thus did the most politic nation of antiquity interpret the occurrence of epilepsy during public business, nor did they hesitate to dissolve a meeting the moment that so apparently portentous an interruption took place.

Even now, when the mind is strengthened by true religion, which, by calming the spirit, adds to the powers of observation and of reasoning, and is destructive of superstition, and which, moreover, imparts just views of the divine government, the occurrence of epilepsy is productive of awe in those who are gifted with reflection; not as manifesting any disturbance in the established order of nature, but as a striking and salutary evidence of the uncertainty of health, a gift generally prized by mankind above all others.

Paroxysm.—The scream with which epilepsy usually commences is one of the most startling sounds that can be uttered. In female auditors it has produced an hysterical fit, abortion, or, as it has been said, eclampsia. We have known it produce in an animal an effect which, although not without something ludicrous in its nature, is calculated to exemplify its astounding harshness. A young lady, while in the drawing-room of an eminent physician, waiting the assembling of a consultation summoned to consider her case, was suddenly attacked with epilepsy. She uttered a scream so piercing, that a parrot, himself no mean performer in discords, dropt from his perch, seemingly frightened to death by the appalling sound.

When, horror-struck by the scream, we turn to the patient, we often find him labouring under a general spasm, more especially of the extensor muscles; his eyes may be discovered fixed and staring, his eye-brows contracted and lowering; he appears to draw back from the beholder with a fixed and threatening look, which, however, it immediately becomes apparent, is but a senseless gaze. The complexion in some epileptics is leaden, in others it is flushed even to duskiess; the muscles are in alternate relaxation and vehement con-

traction, the spasms being what are called clonic. In a girl who was for some time under our care, so violent were the muscular contractions, that her arm was found dislocated after every fit, until by a proper bandage, which she always afterwards wore, this accident was prevented. Burserius describes a similar accident, and tells us that he once attended a young lady whose jaw was found dislocated at the end of a paroxysm; and several authors have observed the teeth fractured by the violent contraction of the muscles which elevate the jaw; the tongue is often protruded, and is then almost always bitten, sometimes nearly through; frequently the sides of the tongue, after the fit, are found ragged and bleeding, having been gnawed by the teeth; from the wound in the tongue, the frothy saliva which is forced from the mouth is often tinged with blood; the neck appears swollen; the eyes roll, or are fixed in a hideous squint, which sometimes continues after the paroxysm is over, and even has been permanent;* rapid nictitation takes place, and the mouth is sometimes strangely distorted. The abdomen is distended with flatus productive of borborygmi. The diaphragm, abdominal muscles, and muscular coat of the bladder, overcoming the resistance of the sphincters, expel the fæces and urine with violence, nor is a discharge from the vesiculæ seminales uncommon. The pulse is rapid, especially at first, but varies much; it is generally full and strong towards the end of the fit, when sweat flows, especially from the head and neck. The breathing also varies; sometimes it is sibilous, sometimes stertorous; sometimes the lips are puffed out by every expiration; at last the breathing becomes full and uniform. The violence of the convulsions gradually abates, and the strong muscular contractions give way to subsultus tendinum; and at last the patient, perhaps previously heaving a sigh, is restored to a degree of recollection; soon after which, exhausted by the violence of the struggle, he drops into a profound sleep, from which he awakes unconscious of his illness, unless admonished of having had an attack by a severe headache; by the state of the tongue; by discovering that there has been some involuntary discharge, which experience has taught him to connect with the fits to which he is subject; by extreme exhaustion, which may continue for several days; or by discoloration of the skin from ecchymosis similar to that which often occurs in whooping-cough.

Death has taken place unexpectedly in a paroxysm of epilepsy, occasioned, as it is thought, by respiration being suspended by spasm of the glottis, or by congestion of the vessels of the brain.

The attacks of epilepsy are not always attended with so horrible a struggle as that which

* *Oculorum bulbos incredibili celeritate sub palpebris clausis rotari observatur, unde in musculis oculorum moventibus magna distractio fit, et incurabiles sæpe tota vita oculorum distorsiones manent.* V. Swieten Comm. §. 1077.

we have described. Sometimes the patient is seized with sickness or great faintness; his sight becomes dim and uncertain, and recollection is lost, together with all muscular power, so that he slips from his chair or falls from his horse, and when his friends run to his assistance, they find him pale and bedewed with cold perspiration, perhaps insensible, but not convulsed. Occasionally he obtains great relief from vomiting; but generally he continues sick, languid, and confused during the remainder of the day. These attacks may often be traced to indigestion, and sometimes require nothing more for their removal than attention to the state of the stomach.

There is yet a slighter paroxysm to be described, indeed so slight that its nature is generally overlooked by the patient and his friends. It takes place thus: the eyes of the patient suddenly become fixed and vacant; if he be in conversation, sometimes he tries to prolong it in a slow, monotonous, gibbering manner. This attempt, narrowly scrutinized, would seem merely an abortive effort to articulate the last word which he had uttered, and which he mumbles for half a minute or a minute, and then recovering, he takes up the thread of his discourse, being soon aware of an interruption of consciousness, which interruption we have sometimes seen an artful attempt to conceal. Some individuals have described this state as one of great mental distress, of perplexity and depression, like a frightful dream; they have an imperfect reminiscence of some overwhelming calamity, or a sense of remorse, for which they cannot assign a cause. This paroxysm is like a short mood of extreme melancholy, at least such an impression the countenance of the patient, which is full of sadness, makes upon the spectator. The returns of these attacks are frequent; they occur several times a day with some. They who are thus affected seldom escape for many days. That this slight and transient attack, which has been called by some French writers "*vertige épileptique*," is truly an epileptic paroxysm, we are of opinion from having observed the chain of thought completely broken; from having seen it in persons who had been affected with falling sickness in its severest form; from having known falling sickness affect patients who had suffered under these slighter fits, and from a recollection of the slighter and more severe attacks being alternate in the same individual. This affection is alluded to by Burserius,* as well as certain other attacks, in which a clonic spasm of only some parts, as of an arm or only of the face, takes place, or in which *all* the senses are not overwhelmed, in the following terms: "There are, moreover, certain degrees of approximation to epilepsy in which the senses are interrupted only for a moment, and scarcely any convulsive motion, or only a very slight one, takes place, the patient not falling to the ground, but continuing to stand. These I should rather name epileptic attacks than actual epilepsy. But if

they are neglected, a transition first to epilepsy, and next to that which is severe and perfect, in general gradually takes place." Heberden briefly describes this affection as follows: "*Postremo animæ defectio levis, quæ modo antecedit justam epilepsiam, modo quasi vicem ejus implet, dum nihil aliud æger sentit præter oblivium quoddam, et delirium adeo breve ut fere ad se redeat priusquam ab adstantibus animadvertatur.*"*

The following case of this sub-epileptic seizure was written by the patient herself, (C. S. æt. 37,) and is highly illustrative. "Even when a girl, I was very nervous, sometimes loosing all my strength. I have also been liable to a complaint in my liver, for which I was rubbed with mercury. I have had working and uneasiness in my feet, which was quite painful. Now, at times while speaking, or while any one is speaking to me, I get a confusion on the subject about which we are conversing, which used to last for some time, but does not now for more than a minute, and when it is gone I have a most violent palpitation. I have it now much oftener, but it does not last so long. I am told I grow pale round my mouth and look rather melancholy for the time, and fix my eyes upon the person with whom I have been talking. I at the same time work my hands, from having a most uncomfortable feeling in them. I am told I always make a noise in my throat, and moan; but of this I am not conscious, and I seem to be in a tremble, my hands shaking. I am tormented with a pain which goes from my chest to my back-bone, and prevents me from drawing my breath, and gives me an inclination to sigh. From my head to my feet I am at times in pain, and I feel as if there were a heart beating in every part of my body. A numbness comes in my hands, particularly at night, and then I have no feeling in my fingers, till by rubbing I get it back. Occasionally I have had numbness and coldness in my tongue. A lump came in the outside of my throat, which often returns with violent throbbing. This I have every evening."† In this patient there was great irregularity in the uterine function. In truth, this was a specimen of uterine epilepsy intermingled with hysteria, which was aggravated by continued anxiety of mind and a diet much too stimulating.

In the much greater number of patients the paroxysm of epilepsy occurs without warning,‡ but some are admonished of its approach by symptoms referable to a disturbed state of the

* Heberden Comm. cap. xxxiii.

† Perhaps we may be allowed to observe that a swelling of the thyroid gland, which is often a symptom of hysteria, has not, as far as we know, been sufficiently attended to. This swelling sometimes disappears and returns, but is more commonly permanent; in its external character it is not distinguishable from bronchocèle.

‡ Sur cent malades, on en trouve a peine quatre ou cinq dont les attaques soient précédées et annoncées par des symptômes précurseurs. Chez les quatre vingt quinze, ou quatre vingt seize autres, l'invasion de l'attaque est subite. Georget, Dict. de Médecine, Art. *Epilepsie*.

* Burserius, vol. iv. §. 264.

brain or of the external senses, similar to those which are premonitory of apoplexy; as for instance, excitement of the mind; throbbing in the temples; turgescence of the veins of the neck; flushing of the face, with cold extremities; giddiness, weight, headach, drowsiness, forgetfulness; disturbed rest, frightful dreams; irritability of temper, despondency; inarticulate speech; flashes of light or sparks of fire seen in the dark; tadpoles, moths, flies, chains, or cobwebs, appearing before the eyes; coloured areolæ around the candle, or any other luminous body; dimness of sight, or only one portion of an object distinctly visible; hissing, ringing of bells, roaring of the sea, or other discordant noises heard; strange and unpleasant odours smelt; disagreeable tastes occurring; numbness in the course of a nerve, or tremblings or convulsions in a limb mounting upwards. Watching or delirium sometimes precede a fit, during which ghosts and apparitions are supposed to appear; and as the fit does not always follow the illusion, many of our ghost stories and supposed visions doubtless have arisen from threatenings of epilepsy or of apoplexy. We knew an individual subject to epilepsy who believed that his mother had visited him after her death. Disorders of the digestive organs frequently precede epilepsy, as pain in the abdomen, salivation, sickness, vomiting, looseness. Sometimes the paroxysm follows hysteric symptoms, sometimes obstructed or painful menstruation; or, lastly, the attack follows the *aura epileptica*, which is a sensation as if a current of air, stream of water, or slight convulsive tremor ascended from a part of the body, or of the extremities, to the head; when the aura reaches the head, the patient falls down in convulsions. This sensation has first been felt in, and seemingly has arisen from, various parts of the body; from the toe, foot, leg, groin; from the finger, hand, arm; from the bottom of the spine, uterus, loins, abdomen, and chest.

Here we would observe, that the epileptic fit does not always take place when the patient is thus menaced with it. Premonitory symptoms of epilepsy often occur; not only vertigo, headach, false perceptions, but convulsions in a limb, or in one side of the face, similar to those spasms to which Bursarius alludes, with weakness, headach, and a degree of stupor; after which the patient recovers, without the convulsions becoming universal, or insensibility being complete. Dr. Prichard considers these as attacks of partial epilepsy, under which head they are described by that eminent pathologist. To us it would rather appear that, like the aura, they are mere threatenings of a fit.

In some patients epilepsy is congenite, in others it commences in childhood, in others in youth, manhood, and even in age. Sometimes, when previously established, it subsides at puberty; and sometimes, especially in females, the disease commences at that important epoch. There is much variety and uncertainty with respect to the return of the

paroxysms. The attacks have been periodic, but much more generally they are irregular in their recurrence. Months, nay years, may intervene between the severer attacks, while the slighter may return daily.* We have preserved no list of the epileptic patients by whom we have been consulted, and cannot state the proportion of males to females, but our impression is that we have seen many more of the former than of the latter; hence the observation of Heberden, distinguished for his accuracy, is, we presume, true with respect to epilepsy as it occurs in the upper and middle ranks of society, "*Feminæ tamen rarius quam viri in eam incidunt.*"†

We have known individuals subject to epilepsy preserve their intellect unimpaired in old age. A very dear friend who was liable to epilepsy, died a few months ago in the seventy-fourth year of his age, whose comprehensive, well stored, and active mind remained unclouded till within a few weeks of his death. But it is often otherwise; many become corpulent, indolent, dyspeptic; others are affected with paralysis, apoplexy, or veternus, or sustain gradual inroads on the intellect, which lead to amentia, the relations of things being no longer perceived or recollected by them: like mere machines, they act as they are induced to do by external influence; no longer able to originate any thing, when they receive an impulse they are carried on as it were by mere habitual training, the power of modifying their conduct by circumstances as they arise being lost. They generally sit all day long staring and drivelling, inattentive to the calls of nature; so that at last their most sanguine and affectionate relatives, despairing of their recovery, become anxious for their death as a release from suffering and degradation. The change which takes place in the expression of the countenance cannot be better described than in the words of M. Esquirol. "*Les traits de la face grossissent, les paupières inférieures se gonflent, les lèvres deviennent épaisses; les plus jolies visages enlaidissent, il y a dans le regard quelque chose d'égaré, les yeux sont vacillans, les pupilles dilatées. On voit souvent des mouvemens convulsifs de quelques muscles de la face.*"‡ While we transcribe from Dr. Cooke's valuable work on nervous diseases the following descriptive passage from Aretæus, we would have the reader take note that it is applicable chiefly to the extreme cases of the *epilepsia cerebialis*. "If the disease be of long duration, patients suffer from it even in the intervals of the paroxysms; they become torpid, languid, and dejected; they avoid the sight and society of men; time does not afford any mitigation of their sufferings; they are often oppressed with watchfulness, and when they do sleep they are terrified with horrible dreams; they loathe food, and digest with difficulty; their natural colour

* Heberden relates a case in which there was an interval of thirteen years between the first and second paroxysm.

† Heberden Comm. cap. xxxiii.

‡ Diction. des Sciences Méd. vol. xv. Art. *Epilepsie*.

disappears, and changes to a leaden hue; they have a difficulty of comprehension on account of torpor of mind and of sense; they are dull of hearing, are affected with a ringing of the ears, and a confused sound in the head; the tongue is unable to do its office, either on account of the nature of the disease, or from injuries which it may have received in the paroxysms; they are agitated by convulsions, and sometimes the mind is so disturbed by the complaint, that persons labouring under it become fatuous or idiotic.”*

Species of epilepsy.—This disease has been divided into the idiopathic and sympathetic species, the former embracing the cases which depend upon an affection of the brain, the latter the cases which depend upon an affection of parts remote from the brain—the *epilepsia cerebialis* and the *epilepsia sympathica*. With respect to the *epilepsia occasionalis*, which is the third species of Cullen, most of its specimens may be considered merely as convulsions symptomatic of other diseases. Thus the *epilepsia traumatica*, *e veneno*, *e scabie retropulso*, a *hæmorrhagia nimia*, a *debilitate febricosa*, *ab hydrocephalo*, &c. ought to be treated of under the head of wounds, poisons, &c. or if considered not as symptomatic, they ought to rank under the head of eclampsia, an acute disease, of which the paroxysm may never be repeated, and not under epilepsy, which is a chronic disease and recurrent.

It must not be denied that it is not always an easy matter to distinguish between the *epilepsia cerebialis* and the *epilepsia sympathica*: the rules for discriminating the one from the other, laid down by authors, are by no means implicitly to be relied upon; and, as the decision of this point is not always practicable, the physician, in the course of an attendance, will sometimes have to change his opinion, for which he ought to be prepared. A dictum of the celebrated Cullen, namely, that in the *epilepsia cerebialis* there are no premonitory symptoms, while the *epilepsia sympathica* is generally announced by an *aura frigida*, has not been confirmed by our observation.

In our endeavour to determine the species to which a case of epilepsy belongs, we may proceed as follows:—First, we may inquire into the state of the natural functions—the state of the appetite, digestion, and nutrition, and into the condition of the secretions and excretions; then into the state of the nervous system; and lastly, if the patient is a female, into the functions of the uterus, especially with respect to menstruation. If we are unable to detect any affection of the nerves, any local irritation, or disorder of a part remote from the brain, we may with probability consider the case as a specimen of the *epilepsia cerebialis*.

In this conclusion we may repose with more confidence, if we discover that the disease is inherited; that the patient has been liable to vascular congestion in the brain from deter-

mination of blood to the head, increased action in the arterial system within the cranium, or obstruction in the system of the veins, to be inferred from flushing of the face, throbbing in the temples, epistaxis, vertigo increased by stooping, dulness or weakness of intellect, tightness across the forehead, headach, false perceptions; that there is any thing peculiar in the form of the head, or expression of the countenance; and that the habits of the patient have been such as to produce considerable or long continued excitement of the brain. Paroxysms of epilepsy which occur late in life in persons who have had apoplexy, or whose diathesis is apoplectic, rank under the *epilepsia cerebialis*; as also do those cases of not unfrequent occurrence, in which epilepsy almost invariably leads to an attack of insanity; cases which differ in two respects from the more common form of periodic insanity, 1st. in commencing with an epileptic fit; and, 2dly, in the mind being much sooner restored to sanity—derangement continuing sometimes only for a few days. It may, however, be worth while to observe, that while differing in these respects, the mental disturbance which follows epilepsy, and *mania periodica*, require the same method of treatment.

Of the *epilepsia sympathica* there are five species, viz. that in which the brain sympathizes with a disordered state of the stomach, of the liver, of the nervous system, of the uterus, or with any part of the body suffering from pain or irritation. The following, then, is our arrangement of the subject:—

I. *Epilepsia cerebialis*.

II. *Epilepsia sympathica*.

Sp. 1. *Epilepsia stomachica*.

- 2. — *hepatica*.
- 3. — *nervosa*.
- 4. — *uterina*.
- 5. — *a dolore*.

1st species.—In addition to many of the common symptoms of indigestion, such as a loaded tongue, unpleasant taste, acid or rancid eructations, *cardialgia*, heavy breath and perspiration, high-coloured urine, fulness of the hypochondria, and foul discharges from the bowels; the appetite in the *epilepsia stomachica* is extremely irregular and capricious; sometimes it is defective, often canine, and a sense of distention of the stomach takes place after meals. Even while the demand for food is exorbitant, it will often lie in the stomach undigested for two or three days; this is frequently the case about the time of a paroxysm, shortly after which we have known an enormous quantity of half digested food vomited, part of which had been eaten at least two or three days before. “*Epilepsia stomachica ea est quam fovet et excitat crapula; cardialgiis, ructibus, anorexia, dyspepsia, nauseis, vomitione, prægressis.*” Sauvages, cl. iv. g. xix.

2d species.—The liver more than the stomach would sometimes appear to be the organ in which this disease originates. Cases have been reported to us in which paroxysms of epilepsy were invariably preceded by change in the

* Dr. Cooke on Nervous Diseases, vol. ii. p. 24.

complexion, and pain and tenderness of the right hypochondrium; and in which by great attention to the liver, when its function became disturbed, attacks of epilepsy have been averted. We learn from Bursarius, that, in certain cases, epilepsy is preceded by pain in the region of the liver, icterus and symptoms of calculi in the gall-bladder; and from Dr. Prichard, that he has witnessed several cases of epilepsy wherein the symptoms which point out the existence of chronic diseases of the liver were clearly discernible. The following is a brief case of the epilepsy hepatica.

"May 6, 1827. Mr. ———, of a highly scrofulous diathesis, has been affected with epilepsy for several years. The fits commenced at the age of thirteen, and were for some time very frequent in their recurrence; what remedies were employed at first does not appear, but of late he has tried a variety of quack medicines. About twelve months ago, after a rapid succession of paroxysms, he consulted Dr. Casey, of Cork, who found him complaining of pain and soreness in the right hypochondrium, his complexion being at the same time sallow, and his stomach disordered, and by whom small doses of a mercurial medicine and bitters were prescribed, by means of which these symptoms were removed, and there was no return of epilepsy for some months; after which, in November, symptoms of great hepatic disorder returned, of which two paroxysms of epilepsy apparently were the consequence. Since which he has had no paroxysm in a perfect form; but he has experienced symptoms which formerly had forewarned him of an attack, and which he designated a "nervousness," namely a sudden tremor with a momentary but slight convulsion, at which time there was always more or less disorder of the hepatic function; when these symptoms occurred, a brisk mercurial purgative was given, and under this simple treatment he has enjoyed a longer exemption from convulsions than since the commencement of his illness."

3d species.—In pursuing our investigation, we ought next to endeavour to ascertain whether the patient, if a female, is labouring or has laboured under hysteria; whether she has been liable to rapid palpitation of the heart, sudden failure of strength, faintings without loss of consciousness, entire loss of voice, anorexia, or any of the more palpable symptoms of hysteria, as the globus or clavus hystericus. Nay, although there be no symptom of hysteria, causes which produce that affection may have been in operation prior to an attack of epilepsy, as sedentary occupation in a close and cold apartment, insufficient food, depressing passions; and if so, much light may be thrown on the case through a knowledge of the diathesis of the patient. Nor ought the inquiry respecting the symptoms which characterize hysteria to be confined to the female; for symptoms which no one would hesitate to call hysterical, if occurring in a female, may frequently be detected in males subject to epilepsy, who are of a nervous temperament or hypochondriacal;

and hence, that we may include both sexes, this species ought to be called *epilepsia nervosa* rather than *epilepsia hysterica*, hitherto the term which has been applied to it.

In patients liable to *epilepsia nervosa*, there may sometimes be observed preceding a paroxysm, an excessive irritability with jactitation, weakness, tendency to delirium, suspicious breathing requiring a constant supply of fresh air; or tinnitus aurium, vertigo, and the wildest hysteric delirium.

4th species.—An inquiry into the condition of the uterine function will sometimes discover the nature of an attack of epilepsy, which may be connected with obstructed menstruation or dysmenorrhœa. The *epilepsia uterina* arises and returns at or about the period of menstruation; sometimes for the first time at puberty, and often in consequence of those causes which check menstruation, as damp and cold feet, excessive fatigue, great anxiety of mind or alarm. In our opinion this species ought to stand apart from the third species, with which it is generally identified, but from which it differs both in its causes, exciting and predisponent, and in the method of treatment which it requires.

5th species.—To this species of the disease belong cases of epilepsy originating in injuries, in which the nerves are wounded or lacerated, or arising from diseases of the nerves. In the Edinburgh Medical Essays and Observations,* a case of this nature is related, in which epilepsy was caused by a cartilaginous tumour of the size of a large pea, which was situated on a nerve. Upon the excision of the tumour the fits ceased. In the same work there is an account of convulsions being caused by a concretion of the size of a nut pressing upon a branch of the sciatic nerve. One such neuralgic affection we have witnessed, but we rather think the convulsions in that case were not strictly epileptic. To this species, also, belong the affections described by La Motte, in which epilepsy was caused by calculus in the pelvis of the kidney: one epileptic, after a violent paroxysm of the disease, voided five calculi, and had no return of the fits.† As these cases, however, are rather within the province of the surgeon, we shall not revert to this species of the disease when we come to explain the treatment of epilepsy.

It must be acknowledged that the symptoms which, in distinct groups, give a specific character to a case of epilepsy, are in some instances confusedly intermingled, whereby the symmetry of our attempted arrangement is disturbed, and, what is of much more moment, the remedial process rendered difficult by contra-indications: thus it would not be easy to say to which of the foregoing varieties the following case belongs, which is presented, not to discourage the student, who with increasing experience will see more clearly that our division of this important subject is founded on

* Vol. iv. Art. 27.

† Vol. ii. p. 20.

just observation, but to shew him that there are difficulties which it will require persevering study as well as the most attentive observation to conquer.

"In the latter end of harvest, 1829, a young lady, æt. 17, who had not begun to menstruate, of a very sturmount habit, and much afflicted with psoriasis labialis, having a dry, scabrous, branny skin, and being liable to hysteria in an aggravated form, was visited for the first time by a physician just as she was recovering from a paroxysm of epilepsy, several attacks of which she has since had at the intervals of one, two, or three months. After the first attack there was a sense of fullness and tension in the head, with symptoms of hepatic congestion and torpor, all of which yielded to a moderate bleeding from the arm, together with the use of calomel and pulvis Jacobi, followed by a draught of the infusion of senna and the compound decoction of aloes; and subsequently the shower-bath, and diet of easily digestible materials, together with tonic medicines. Her tongue had usually been coated, the digestive function depraved, as appeared from anorexia and a very capricious choice of food; the alimentary canal very torpid, requiring the continued use of various active purgative medicines. The paroxysms appeared some of them to be averted by a pill of calomel over night and a purgative draught in the morning, so that indigestion seemed to be the chief radix morbi."

Pathology of epilepsy.—That there will in general be found, on dissecting the bodies of those who have laboured under falling sickness, some exemplification of diseased structure in the cranium, subjacent membranes, cerebrum, cerebellum, or spinal canal, works of morbid anatomy, and treatises on epilepsy, have taught us to expect: they shew that after death we may count upon finding a part of the contents of the cranium affected through the operation of some irritating cause. In some dissections is discovered exostosis, or thickening of the bone, which indeed may be a consequence rather than a cause of disease; in others, inflammation or ulceration of the membranes of the brain, of its surface or substance; in others vascular turgescence; effusion of various fluids—bloody, serous, gelatinous, purulent; induration or softening of the brain; tumours sometimes are detected, whether scirrhous, fatty, or sarcomatous; and lastly, tubercles or hydatids: but what *may* be disclosed by any one dissection about to be performed, whether an appearance connected with some change in the structure of the bone, membranes, or the brain itself; nay, whether *any* morbid change will be discovered, a cautious physician would not venture to predicate. The following is one of many quotations which we might produce to shew that dissection hitherto has given us but little aid in ascertaining the cause of epilepsy: "Sed et fessi fuerunt summi in arte viri, atque in rebus anatomicis peritissimi, quod in cadaveribus hoc morbo defunctorum nihil invenerint sæpe quod culpæ poterant."*

* Van Swieten Com. s. 1872.

Even the brothers Wenzel, who have produced a monograph on this subject of the highest order, in which we recognize just principles of investigation, ability, and zeal, after an inquiry continued for a good many years, and the careful dissection of above twenty epileptics, confining their observations to idiopathic epilepsy, to the exclusion of those cases, "*en qui cette maladie peut être produite par des vers ou autres causes extérieures et matérielles*," and arriving at a conclusion that the disease is seated in the sphenoidal bone, in the pineal gland, and the pituitary gland, but chiefly in the latter, have added but little to the pathology of epilepsy.

Admitting their conclusion to be just, it will not satisfactorily explain the nature of the disease, nor lead to any practical improvement, the great objects to be obtained from the cultivation of morbid anatomy. There seems to have been the greatest diversity in the appearance and condition of the pituitary gland.*

* As it would appear from a paper placed in our hands by Dr. Tweedie, which was written by his friend Dr. Sims, of London, that in the French translation of the work of the Wenzels by M. Breton, ann. 1811, the German word *hernanhang*, which ought to have been translated *gland pituitaire*, has been rendered *cervelet*, we are induced to lay before the reader in this note an extract from Dr. Sims's paper, in which an accurate account is given of the labours of the German pathologists.

"The Wenzels regard as a pathological circumstance a peculiar thinness of the sphenoidal bone and of this part of the base of the skull, when compared with the ordinary thickness of the other bones; variations in the position, curvature, and size of the clinoid apophyses; which destroy the natural symmetry of the bones of the basis, and occasion changes in the capacity and form of the sella turcica. These have an influence on the brain and pituitary gland.

"The pineal gland, in several cases, was altered in colour; in ten it was a pale grey; a brownish yellow vesicle on its upper surface is noticed; in all it was softened; in nine it was much smaller, in two much larger than natural.

"In the pituitary gland the principal changes were observed, some of which certainly would require the close inspection of a practised eye to discover: an unequal and furrowed appearance of the upper surface—in two instances a muscular appearance as in old people; excavations, or loss of substance of the upper surface; depression along the anterior margin; alterations of colour, as various shades of red verging to black, pale grey, yellow, brownish yellow, and pale white. In three cases it was very soft; in five, firm, compact, and of unnatural hardness, considerably enlarged, with an effusion of thick lymph between the two lobes. In seven, of prodigious size. The most important alterations existed in the interior: in ten cases, at the point of union of the two lobes, there was a yellow, solid, friable matter, which might be raised in bits; this substance almost always (independent of the separation of the lobes) occasioned a loss of substance. In five cases there was a viscid semifluid lymph between the two lobes. Patches of white, or brownish solid lymph on the superior surface of the gland; the anterior lobe enlarged, and containing a substance resembling pus; the lobes joined without intermediate surface; the lobes separated from each other, the upper surface inflamed.

"In some instances the infundibulum was firmer than natural; in one instance an effusion of lymph resembling false membrane was deposited around a

Its colour was not uniform, nor yet was its consistence. In some cases it was very soft, and in others preternaturally hard; and in respect of its size and structure there was also great diversity. The Wenzels, we conceive, have merely opened up a new path—a path which ought to be explored by future inquirers notwithstanding the discouraging remark of M. Esquirol, “de toutes ces recherches, particulièrement de celles de Bonet, de Morgagni, Baillie, Greding, Meckel, Wenzel, que pouvons-nous conclure? Rien, sinon que ces mêmes altérations ont lieu chez des individus qui ne sont pas épileptiques, comme Wepfer, Lorry l’ont prouvé. Avouons franchement que les travaux de l’anatomie pathologique n’ont jusqu’ici répandu aucune lumière sur le siège immédiat de l’épilepsie.”*

Proximate cause.—Nothing can be more obscure than the proximate cause of this disease. As convulsions similar to those which attend epilepsy may be produced by the application of an irritant direct to the brain; as every part of the frame is agitated during a paroxysm—all the external senses often being morbidly affected just before the paroxysm, the whole muscular system agitated during it; and as not only the animal but the vital functions are universally perturbed, the proximate cause must be seated in the sensorium commune, as being the only part capable of exercising such an influence over the whole body; but the nature of the disorder upon which the epileptic fit depends will probably never be discovered. It cannot be vascular distension, since convulsions are often a consequence of loss of blood, (no other cause at the same time operating,) and may be removed by stimulants. It cannot be vascular collapse, since convulsions sometimes depend upon plethora, and are relieved by spontaneous hemorrhage or by bloodletting.

In this disease we are unable to lay hold of the first link in the morbid catenation. It is generally thought that the aura epileptica is an irritation which first takes place in the sentient extremity of a nerve, and is thence conveyed along the affected nerve to the sensorium, which is thus thrown into disturbed and irregular action, influencing the whole body; but to us it would appear that the aura epileptica is not an irritation of a nerve in the part from which it seems to arise, for then it would take the course of the nerve instead of passing along the integuments; but that it is a reflex sensation, caused by a morbid process going forwards in the brain, or a part of it—that it is a false perception—a mere symptom

portion of it; in another part it was red and inflamed.

“Several other morbid appearances are noticed. Excrescences on different parts of the basis of the cranium; caries of the bones; effusion on the internal surface of the dura mater, and on the arachnoid lining; variations of the convolutions of the brain, of its magnitude and colour; in the ventricles, corpora striata, thalami nervorum opticorum, tubercula quadrigemina. In fifteen of the dissections, the cerebrum and cerebellum were perfectly healthy.”

* Diction. des Sciences Médicales, Art. *Epilepsie*.

of an unexplained disorder of the sensorium, as much as tinnitus aurium, or muscæ volitantes, or numbness in a nerve, or pins and needles, as a certain pricking sensation is called by paralytic patients. It would be vain to investigate the essence of a disease, in which there is the utmost uncertainty even in the first stage of our inquiry; in which dissection, instead of affording assistance, rather perplexes us by the multiplicity and diversity of the changes of structure which it discloses. Moreover it would appear that so long as we are ignorant of the nature of the healthy function of the brain, in what manner its influence over the body arises and is maintained, the deviation from the healthy exercise of its function which constitutes the proximate cause of epilepsy must remain sub judice.

Predisponent cause.—According to systematic writers, the predisposition to epilepsy is supposed to depend on “great mobility,” on “a peculiar liability to excitement and collapse;” on “a liability to be influenced by those causes which are applied to most persons with little or no effect.” This condition connected with “a greater degree either of sensibility or irritability, it is conceived, is generally derived from original stamina, and may more particularly depend either upon debility or upon a plethoric state of the system.” We must, however, observe that we have known epileptics, who did not give way to strong emotions upon slight impressions, who were with difficulty excited, and who pursued every purpose with a manly constancy; and hence, without denying that a state, not easily definable, of mobility, is a predisposing cause of epilepsy, we conceive that it is by no means the only predisponent to that disease. An opinion on this subject which we hold, we think will probably not obtain favour; and yet, as it has not been hastily formed, we consider it a duty to put it forward, that it may be verified or disproved by future observers. We conceive that epilepsy is as certain a manifestation of the strumous diathesis as tubercular consumption, psoas abscess, hereditary insanity, or certain congenital malformations or defects of organization which are inherited only from scrofulous parents. Epileptic patients are of the habit of body in which scrofula occurs. We have no recollection of a case of cerebral epilepsy in a patient, who, when due inquiry was made, did not appear to inherit a strong disposition to scrofula. It must be admitted, however, that there are many epileptics in whom there exist none of the more common symptoms of scrofula.

That epilepsy is a hereditary disease is generally admitted. If, when consulted by an epileptic, we make diligent inquiry, we shall find that, although direct progenitors, father or mother, may have escaped, yet some member of the family (uncle or aunt, grandfather or grandmother,) has been subject to fits. As Boerhaave has observed, “silente sæpe morbo in genitore, dum ex avo derivatur in nepotem.” If epilepsy for the first time occurs in a family, it has appeared to us that it has been in conse-

quence of the strumous diathesis having been exalted by the intermarriage of two persons inheritors of that condition or tendency of the constitution, and which it has been in a yet more remarkable degree if the parents were of the same blood and nearly related—we may then expect, if an epileptic patient has several brothers and sisters, that his case will not be a solitary one in the family.

Occasional causes.—Patients, especially those who have had only two or three attacks of epilepsy, are ever ready to consider them as accidental. One attack is brought on by a fright, probably the most frequent exciting cause of the disease; another by over fatigue; one by confined bowels; another by a strong purgative; one by fasting, another by a surfeit; and it cannot be denied that very many attacks of epilepsy may naturally enough be traced to some inattention to the organs of assimilation, especially in the form of excess in the use of fermented liquors. There was lately in Steevens's Hospital, Dublin, a patient who some twelve or fifteen years ago had a fracture of the skull, which left a depression of the bone. After the accident occurred, he was subject to epilepsy whenever he indulged in the use of intoxicating liquors: at last he was induced to lay them aside, and ever since he has been without an attack of epilepsy, and is now an able-bodied watchman. "I have observed," says Fothergill, "that epileptics are often extremely incautious with respect to diet; that children highly indulged are liable to the disease; that in every other period of juvenescence, and in middle-aged adults, if they were attacked with the disease, it was when they had either committed some excesses, or by one means or another were plethoric; and that in habits subject to epilepsy, the disease seldom recurred without either an habitual indulgence in eating, or a neglect of necessary exercise."

The occasional causes of epilepsy may be divided into two classes. 1st. Joy, anger, suppressed discharges, repelled diseases, elevated temperature, bodily over-exertion, drunkenness, prolonged sleep, surfeiting, congestion of the bowels, obstructed or painful menstruation. 2. Opposed to these are terror, grief, disgust, exhaustion of mind from intense application to business or study, vigilance, inanition, hypercatharsis, venereal excesses, hemorrhage. "Parmi les causes excitantes de l'épilepsie la frayeur tient à-coup sur le premier rang. La colère et un chagrin profond, la masturbation, et les excès vénériens paraissent, après la frayeur, tenir le premier rang parmi les causes de l'épilepsie."* We read of epilepsy being caused by imitation. An attack of epilepsy, when witnessed by a number of unmarried females in a church or school, has often led to convulsions spreading from one to another, till a great many are affected. Dr. Whitt describes this affection in the following words: "There is a disease very common in the islands of Zet-

land, which is known there by the name of the convulsive fits. It begins with a violent palpitation of the heart; soon after which the patients fall to the ground, unless they are supported; their arms and legs are alternately contracted and relaxed; and in some cases their joints become so rigid that they cannot be bent. Their respiration seems to be difficult, and they cry terribly while the fit lasts, which is generally less than a quarter of an hour. This disorder seldom attacks married women; but young women, and even girls of ten or twelve years of age, are liable to it. Some boys and two young men in these islands have also been affected with it. In the church or other public meetings, as soon as one is seized, all such as have formerly been subject to the distemper are attacked with it, which often occasions great disturbance." These attacks, there cannot be a doubt, are not epileptic, but like certain more recent exhibitions in churches are clearly referable to sympathetic hysteria.

Of the occasional causes of epilepsy, it is justly observed by Dr. Cooke, that "some are stimulants producing an increased action of the brain, while others are sedatives, operating so as to diminish its energy." When there is a predisposition to epilepsy, a cause of either kind, productive either of excessive or defective action, may interrupt the equable transmission of the sensorial power by means of the nerves, and thus occasion a fit; and hence it would appear desirable to retain every patient who is subject to epilepsy in a state equally distant from plethora or from undue emptiness of the cerebral vessels.

Diagnosis.—We have reason to think that not only eclampsia, but hysteria; cataleptic hysteria; sympathetic hysteria, the disease of religious sects among whom enthusiasm is permitted to usurp the place of sobriety; catalepsy; cataleptis delirans; extasis, have been considered as specimens of epilepsy. The student, therefore, must acquaint himself with these diseases, as also with the history of feigned epilepsy, which, not merely in the military hospital but in private practice, he may be called upon to distinguish from the genuine disease. Let him bear in mind that if a fit commenced with a scream, if it was characterised by insensibility, convulsions, and foaming at the mouth, if it ended in sopor, and if the tongue were wounded or even gnawed at the edges, there can be but little doubt that it was epileptic.

Prognosis.—The prognosis in epilepsy embraces two heads of inquiry, viz. first, the danger to be apprehended from the paroxysm; and, secondly, the probability of a return.

As epilepsy sometimes proves suddenly fatal during a paroxysm, our opinion must be delivered with a salvo in reference to such a contingency. To form a judgment of the amount of danger, we must, first, endeavour to ascertain the species of epilepsy to which the case belongs; cerebral epilepsy being attended with more danger than nervous, nervous than gastric

* Diction. de Médecine, Art. *Epilepsie*.

or hepatic, and these again than uterine: but we must not forget that the sympathetic species of epilepsy may, by repetition, acquire the character of the idiopathic, and be attended with equal danger. Secondly, we may oftentimes judge of the danger of the attack by the symptoms which precede it; thus, in the cerebral species, danger may be apprehended when the preceding symptoms indicate a fixed disease of the brain, as intense pain, vigilance, delirium; when inroads have been made upon any of the mental faculties; and when there have been threatenings of paralysis. Thirdly, we are influenced by the violence and duration of the paroxysm. Those severe paroxysms which continue many hours often terminate in fatal exhaustion, or in an apoplectic state. Hence coma, after the convulsions, is truly alarming, as it shows that apoplexy has actually begun.

The probability of the return of the fits will, in like manner, be greatest in cerebral epilepsy, then in nervous, next in gastric and hepatic, and least in simple uterine. In cerebral epilepsy the fits will with most likelihood return in the cases in which the disease is inherited, in which the patient has a peculiarity in the configuration of his head and expression of his countenance, and which have been long established. Of the *epilepsia stomachica* and *hepatica*, the cases will probably be most obstinate which exist in connexion with habits of self-indulgence and with weakness of character. Of the *epilepsia nervosa* the stamina of the patient will in general decide our opinion both in respect of danger and repetition; indeed, in every species of epilepsy recurrence will be more probable in a constitution defective in point of original vigour, or impaired by excess. In the *epilepsia uterina* we have most hopes of ultimate recovery, inasmuch as epilepsy will frequently cease when a change takes place in the function of the uterus; as, for example, at the appearance or reappearance of the menses, at marriage or during pregnancy.

We are inclined to think that epilepsy will be found more inveterate when it occurs in patients who are affected with chronic cutaneous affections. To lepra, psoriasis, ichthyosis, and porrigo, epileptics are peculiarly liable.

Treatment.—In general, a physician now-a-days may unreservedly explain his views, to such patients as are possessed of good sense and temper, of the nature of their malady and the remedial process about to be employed,—nay, in some instances, may explain the doubts which are suggested by the former and the uncertainty of the latter, while at the same time the solid ground on which he builds his hope of achieving a cure is clearly pointed out. But such a procedure with nervous patients would be highly injudicious. Not only are such patients, by constitution, infirm of purpose, but by disease are they often rendered additionally irresolute, and, in consequence of the fears which disease engenders, they are a prey to every pragmatical relative or acquaintance or volunteer prescriber, who may choose

to insinuate doubts and apprehensions, suggest the necessity of changes, and damp and disconcert the medical attendant.

When he undertakes the treatment of a case of epilepsy, the physician ought in the first place to study the patient's disposition, in nervous illnesses it being generally of as much importance to distinguish the shades of character as the shades of disease; and, having penetrated into the interior of his patient's mind, he must there obtain an ascendancy not merely by knowledge of disease, but in virtue of that influence which is generally obtained by calmness of manner and consistency and decision of conduct. We venture to hazard an observation with respect to physicians of equal skill in the medical treatment of nervous diseases, that they who are not communicative will be more confided in and more successful than they who think aloud and explain all their views and plans.

It would lead us away from our subject, otherwise we could easily show the necessity that the physician is under of acquiring and retaining a complete control over the mind of his epileptic patients, and of inspiring them with hope. We may be permitted to state, in support of this observation, a fact which we have often witnessed, namely, the temporary advantage which is generally derived from a change of measures. When an epileptic patient is placed under the care of a confident empiric, or of a physician who is in great repute, the disease will often be suspended for a considerable time, and to the eye of a sanguine person appear cured; while on the other hand, after a long suspension, when the disease returns, such disappointment is produced as to fill the patient with the gloom of despair, a state of mind which would seem to renew the energy of those causes upon which the fits depend, and hence they occur at shorter intervals and with greater violence than ever.

The empiric, well knowing how much depends on confidence, has various methods of fixing unstable minds; he cajoles and blusters, and with equal power of fulfilment he promises and threatens; he knows that he may draw upon the imagination of his patient to any amount, and that his draft will be honoured; that the mystery with which he clothes all his measures is often the cause of his success, and hence he provides his own remedies, and invests them with supposititious activity. Give a patient a few grains of liquorice-powder, and let him be told that he has just swallowed part of the skull of a malefactor, (which once was considered a sovereign remedy for epilepsy,) or that this powder contains a substance of which, according to the German dreamer, a thousandth part of a grain is the proper dose, and you often may thus cure a disease which is anything but imaginary. In Ireland, epilepsy has often been cured by the priest, who is supposed by the credulous of his own communion to be gifted with the power of working miracles of healing, a power claimed for the Roman Catholic Church, even by her most enlightened mem-

bers. Uneducated adherents of the Church of England, and even the presbyterian, both in such matters equally credulous, often successfully apply to the same functionary to be cured of fits. He sometimes begins the curative process by giving two or three very powerful emetics; but he chiefly relies upon obtaining dominion over his patient's mind, an art in which he is often eminently skilled, and which he is the better able to practise, as probably he implicitly believes in his own supernatural power. If the epileptic be a Protestant, the priest signifies that the prayers which he offers up, the virtue with which he is endowed, are his, only for the benefit of the members of his own church; the patient, overpersuaded probably by his friends, goes to mass with reluctance, as a temporary expedient to qualify him for the intercession of his spiritual physician, by which means the latter gains an advantage over the disease. A struggle has taken place in the patient's mind, in which conscience is laid prostrate; a great and a permanent moral impression is made, which, especially if the disease is nervous epilepsy, sometimes ends in the fits being suspended, and the patient becoming a devoted adherent of the Church of Rome, to whose interests, by his belief in the superhuman power of her clergy exercised in his behalf, he becomes more attached than if he had been born within her pale; and confidence in the agency through which he has obtained relief, we doubt not, sometimes renders it permanent. Such is the nature of modern miracles, and such the principles by which even protestant clergymen have been enabled to take a part in a farce equally disgusting to all who are able to distinguish between true religion and superstition.

A successful empiric, who by various practices had for a long time sustained the hopes of a young lady who was afterwards under our care, one day observed her, while under a sense of faintness, having recourse to sal volatile; this he eagerly snatched from her, and throwing up the sash he violently dashed the vial upon the pavement, at the same time declaring, with well affected displeasure, that if he ever heard that she had any medicinal substance in her possession which was not given to her by himself, he would never see her again, as his remedies were so delicately combined, that, by admixture with any other drug, their efficacy would be completely destroyed.

When the extrinsic occasional causes of epilepsy are removed or guarded against, the paroxysm, as depending upon associations established within, will often return with equal violence. Against epilepsy thus become habitual and almost periodic, well sustained hope, whether rational or but a "fair fallacy," as were the amulets employed of old, will be found more efficacious than any other condition of the mind. Sudden alarm, indeed, has been called into assistance as an anti-epileptic remedy; but, with Dr. Cooke, we agree in thinking that terror cannot be employed in the treatment of epilepsy, as being a remedy not sufficiently under controul. From the annals of medicine

we learn that there were other influences formerly much in vogue, which, acting upon the mind alone, must have produced permanent feelings of disgust; as for example, the following medicines, which may be considered as a curious specimen of the articles of the *Materia Medica*, which, in former times, were derived from the animal kingdom:—*cineres talpæ, muris, corvorum; hepata ranorum; testicula et urina apri; dentes humani pulverisati; hepar hominis comestum; sanguis hominis recens occisi; sanguis patris; secundina humana; stercus humanum*: there are other abominations of the same kind, unnecessary to specify, the use of which, Erastus alleges, was taught to mankind by the devil; but without calling in question the active malignity of our great enemy, we are of opinion that man, when left to his own inventions, is fully equal to the discovery of these and a multitude of other therapeutic agents of equal ineptitude.

We have known regular physicians, aware of the advantage which may be derived from keeping the imagination under the agreeable excitement of hope, practise upon the credulity of their patients, as we conceive, very unworthily. We once possessed a prescription written by a physician of some name in Paris, in which the chief remedy prescribed by him was a polished piece of jasper or jade, which he ordered to be inserted under the skin of an epileptic patient's arm. Had he ordered the words of power which were supposed, by believers in the art magic, to be inscribed on the ring of Solomon, or any other talismanic characters of equal value, to be engraved on this anti-epileptic fossil, his charlatanism would have been more perfect. The regular physician must not practise deception even to forward the interests of benevolence, but he may practise reserve, which will often answer better than all the mystifications of the empiric. Let it be matter of agreement, when he undertakes the treatment of a case of epilepsy, that the patient shall not know the nature of the medicines to be prescribed. Were we, in certain cases, to send our prescriptions to the apothecary sealed up, the medicines so ordered would produce effects which would surprise even the prescriber himself.

It would be superfluous to dwell upon the importance of diet in the treatment of chronic diseases. In such diseases great improvement will sometimes arise from mere change of diet, how unobjectionable soever the diet may have been formerly. If, however, a change is recommended when the individual first comes under our care, it behoves us to explain the reason of the change; let us not, as some have done, change a patient's diet in such a manner as to abate his confidence in his former physician, who may have treated his case with judgment.*

* Some practitioners living in a thoroughfare, or in towns in which the population is constantly fluctuating, thinking that the character of their professional brethren at a distance is a matter in which they have no concern—thinking, moreover, that any means of advancement is lawful—ab-

It is needful to stipulate that our patient shall no longer yield to his appetite or inclination. He must move by fixed rules. He must eat only what is placed before him by order of his physician, not asking to have his food varied or enlarged. We do not exaggerate when we affirm that not one individual in ten, labouring under chronic illnesses, strictly observes the rule of diet which is appointed for him by his physician. Drunkenness, in the middle ranks of society, is much less prevalent than formerly, but epicurism in eating much more so. The affected delight with which some popular writers have expatiated on the refinements and indulgences of the table has been, we fear, supposed real, and has given a stimulus to sensuality much to be deplored, especially among young men, many of whom now put no restraint upon their appetite for rich and savoury food, while on the pleasures of the table they descant as shamelessly as if they were fit only for the society of Apicius. In general there is no difficulty in persuading patients to relinquish intoxicating liquors, which, as almost every sensualist is aware, seldom fail to produce painful exhaustion in proportion to pleasurable excitement, and which are well known to unfit those who habitually indulge in their use for animal gratifications which are more prized; but very great indeed is the difficulty which we encounter in securing a strict acquiescence in our injunctions with respect to food; and if this cannot be accomplished, it would be well that the physician at once should decline the care of an epileptic patient.

Having paid some attention to the proceedings of empirics, foreign and indigenous, regular and irregular, we venture to say that we may sometimes be taught by them useful lessons; and we ought not to decline assistance even from such sources: in this case the end will justify the means employed. There was some years ago, in Dublin, an outlandish person, said to be from Germany—a high German doctor, although by some it was alleged that he was a native of Ireland, and born in the *kingdom* of Kerry—who professed to cure epilepsy. His appearance was such as to strike a vulgar mind with awe, while one who had pleasure in the grotesque or fantastical, or a taste for the antique, could scarcely help being amused by the public exhibition of an individual who appar-

ently belonged to an earlier and more rude and credulous age of the world. With measured pace and serious aspect he paraded those parts of the city which are most frequented, displaying what the refined taste of our youth has rendered no longer a novelty—a beard like that of an adult goat; behind him, almost in lock-step, there marched a tall fellow in a gaudy livery—light blue, abundantly tricked out with silver lace. Jan Stein, the shrewd observer of water-doctors and mountebanks, never painted a more characteristic pair than the solemn leech, whom we have slightly sketched, and his self-important follower. At first, trade was brisk with this adventurer; but he soon left Ireland, having discovered, to borrow an illustration from the agriculturist, that ground made to yield too rich a crop is thereby soon impoverished; and probably he also found that in no community is there a keener perception of the ludicrous or a juster estimate of character than among the more respectable part of the inhabitants of Dublin. He held some of the opinions of the Nazarete, for he told his patients that they must not cut their hair, “in which,” he generally added, “lay the strength of the body,” and he inhibited the use of wine and all intoxicating liquors, a restriction not calculated to advance his reputation in Ireland. But to have introduced this original to the reader would be mere impertinence, were it not that there was a point in the regimen which he prescribed worthy of adoption. He ordered his patients to walk, those who were not enfeebled, twelve, fifteen, or even twenty miles a day. They were to begin by walking a moderate distance, and they were gradually to extend their walk according to their ability. In some of his patients a great improvement took place, both with respect to digestion and muscular strength, and this was so apparent in a short time, that ever since this luminary shone upon the metropolis of Ireland, most of our patients, affected with epilepsy, have, by our advice, been peripatetics. We recommend those who are subject to this disease to walk as far as they can without much fatigue. We do not prescribe one long walk, but several in the course of the day of moderate length. Delicate females have thus been trained to walk eight or ten miles, by making them sit or recline when they were fatigued, and again move on when rested. Females of the hysteric diathesis, who are liable to epilepsy, must pass as much of their time as possible *sub dio*, driving, boating, or even sitting in a sheltered place, if they are unable to walk without being fatigued, muscular exhaustion being generally hurtful to them.

In prescribing a rule of diet suitable to all epileptics, moderation in quantity and simplicity in the preparation of food are indispensable points. If the diet of an epileptic has been either too high or too low, it ought to be changed. We conceive the diet which would best preserve an individual, liable to scrofula, from an attack of that disease, would be best suited to a patient liable to epilepsy. Fer-

ruptly change the measures of their predecessor in attendance, as it would seem, to obtain confidence at his expense. If, for example, a dyspeptic patient has been permitted to take animal food only once a day, they will order it to be taken at every meal. Change of air, of occupation, a mild purgative regularly taken, and perhaps even for a limited time, a full diet after a restricted one, will often produce a sense of great improvement, which it is generally thought by the patient himself might have taken place earlier had his former physician been more skilful. The patient returns home full of erroneous opinions relative to diet, soon to experience an aggravated return of his sufferings, and fondly imagining that there is but one physician in the land who understands his case. Innumerable are the phases of quackery, inasmuch as it is applicable to every species of credulity and mode of folly.

mented liquors, however, should be in general altogether withheld. Flesh meat ought to form the principal part of one if not two meals in the day; and milk, if it agrees, that is, if it does not retard digestion, which it is less liable to do when fermented liquors are laid aside, is the article next in value. The epileptic ought to be trained so as to be in good wind, or, in other words, his muscles ought to be in a state of the utmost strength and firmness. If we permit ourselves to take a lesson from empirics, we may surely avail ourselves of such information as may be derived from a brotherhood at least as respectable, namely, the gentlemen of the *fancy*, as they are called, or we may have epileptics trained as were the *athletæ* in ancient times.

When the patient leaves his bed in the morning, he may have a rusk or a slice of toasted bread with an egg beat up in a teacupful of warm milk and water; then let him dress, make all needful arrangements, and walk three or four miles. Two hours or more after he has left his bed, let him have his second meal,—milk, or cream in water, or cocoa, with bread a day old and good butter. It may be observed that wheat flour is very generally adulterated with bean and potato flour, both of which injure the quality of bread, and that butter is much oftener rancid than good. Let the patient rest for three hours after breakfast, and this will be the best time to devote to business or education. Then he must again walk, if an adult possessed of sufficient vigour, from five to eight miles. At from five to six hours after his second meal let him have a third, consisting of meat-of the best quality,—mutton excluding fat, poultry, game, or very tender beef, roasted or boiled, of which an adult must not eat more than six ounces; bread, and one moderate helping of tender well-boiled vegetables; of drink—not more than a common tumblerful must be taken, distilled water, Seltzer water with a little milk, or toast and water, being equally proper. Then the individual may rest for two hours, but we would not have him lie after meals as some have recommended, this having appeared to us to retard rather than to promote digestion, probably by disturbing the circulation: he may stroll in a garden, read an amusing book, or chat with an agreeable friend, only such occupation being permitted as will not raise the pulse by one beat; he may then resume more active exercise for an hour or two. In five or six hours after dinner a light supper may be taken, consisting of not more than four ounces of meat with bread, or of a cup of milk with a water biscuit. The rest of the evening may be spent in cheerful society, in a large airy room, not overlighted nor overheated, but sufficiently warm to prevent that chill which in the latter part of the day often follows very active exercise; and every occupation by which the mind is depressed, or is excited and thereby subsequently exhausted, must be avoided. The patient must be in bed at eleven and up at six, nothing in general being more hurtful to epileptics than sleep unnecessarily prolonged.

The scalp in all epileptics ought to be shaved once a week, (a few ringlets at the temples and in front being permitted to grow,) and daily well rubbed with a flesh-brush after the tepid shower-bath, or what answers nearly as well and gives less trouble, after pouring a flaggon of tepid water on the head inclined over a large basin. The hat or cap worn must be of the lightest kind, a straw hat, or a light foraging-cap of cloth, which may be replaced, when within doors, by a night-cap of woven silk worn single. The patient may gradually bring himself to sleep without a night-cap, and without curtains, both of which lead to effeminacy; with his shoulders and head raised and his feet well protected from the cold, in a chamber as large and airy as possible, and without a fire; there may, however, in winter, be a fire in his dressing-room, or his bed may be warmed. The temperature of his extremities must always be supported by means of exercise, friction, or proper clothing.

A patient liable to epilepsy must not be permitted to ride or to hold the reins in a carriage. The grates in all the apartments which he frequents ought to be guarded by a deep and strong fender; he ought to avoid the streets of a crowded city, in which the whirl of carriages, the tide of human beings, the stunning confusion of sounds, and the multiplicity and distraction of objects, produce a vertiginous hurry of thought, which to him is ever dangerous. He ought not to walk near water. One of our earliest patients, a fine young man of twenty, came to an untimely end, in his own garden, by falling into a runnel, in which he was drowned, although the water was not more than four inches deep. Lastly, if his circumstances admit of his having an attendant, the epileptic ought never to be alone. His companion ought to be provided with a nervous draught, consisting of camphor mixture and ether or ammonia, by taking which there is reason to think that the paroxysm may be averted in the gastric or nervous species of epilepsy; with a wedge of soft wood to interpose between the teeth; with a piece of broad tape to be applied to the superior part of the limb, if the paroxysm should commence with the aura in the extremities; and with an air-pillow to inflate, and place under the patient's head, when he is attacked in the open air. If the attack takes place in his chamber, the patient ought to be laid on his back on a French bed, with at least one attendant standing on either side to prevent him from injury during the struggle. If he is much flushed, his head and shoulders ought to be elevated, the warmth of his extremities supported, while at the same time air is freely admitted into the room. All attempts to make him swallow, or to stimulate the nostrils, are improper. A medical practitioner ought to be sent for and ought to remain in attendance while the struggle lasts. In a first attack, if the fit is severe, blood ought to be procured from the temporal artery, a precaution which will also be necessary in patients of an apo-

plectic diathesis, whensoever they labour under a prolonged fit of epilepsy.

Most of the foregoing observations apply to every case of epilepsy. Having endeavoured to determine the variety to which the case belongs, a point in general overlooked by the nostrum-mongers, we have now to point out the specific treatment which will be required. We are in the first place to ascertain whether there exist any symptoms of present danger; and, secondly, to apply ourselves "to the more continued treatment required in the disease considered as a chronic affection."^{*}

Epilepsia cerebialis.—If the case belong to cerebral epilepsy, we must endeavour to discover the condition of the vessels with respect to increased action or congestion; if in a state of excitement or turgescence, they must be relieved without delay, by means of general or local bleeding, or by antimonials, with mercurial purgatives, and the antiphlogistic regimen. After every paroxysm, as soon as the patient awakes from that sleep which is part of the crisis, he ought to be examined with care by a medical practitioner. We conceive, were this uniformly done, and the necessary treatment immediately adopted, that in many instances the subsequent attack would be milder and more distant, the faculties of the mind would be less endangered, and the probability of ultimate recovery would be greater. Many chronic affections are merely a series of imperfect recoveries from attacks of acute diseases. This we have seen exemplified on a large scale in the House of Industry in Dublin, which in former times was filled with paupers, the victims of poverty and intemperance, mostly labouring under chronic disorders of the viscera. Many of these outcasts from society passed much of their time in the subsidiary hospitals, to which they were sent when they were affected with febrile attacks, of which a considerable portion of them died; each recurrence of fever assuming a darker complexion in consequence of recovery from its precursor being incomplete. In epilepsy, if due attention were paid after every return of the convulsions to establish the fact of perfect recovery, we are persuaded that the patient might often preserve his place in society, instead of becoming from chronic disease of the brain, originating in or aggravated by the severe paroxysms, a mere driveller, as is the lot of many an epileptic in the latter part of his life. And this view is strengthened by the fact, that some patients are reduced to idiotism, not so much by the natural course of disease, as by vicious habits in which they indulge, which not only confirm the predisposition to epilepsy, but injure the brain and nervous system: "L'abus des liqueurs alcooliques, les excès veneriens, et la masturbation aggravent l'épilepsie et précipitent la perte de la raison."[†]

The paroxysms of *epilepsia cerebialis* chiefly occur, to use an expression of Fothergill's, "in the plenitude of health;" and when this

is the case, we may pursue the plan about to be recommended with more confidence.

In treating this form of epilepsy we apply the principle of revulsion, explaining that term, not as the driving back of the fluids from one part to determine them to another, but simply as expressive of the relief to be obtained for an organ in which a morbid process is going forward, by inducing a more vigorous state of the circulation in other organs, or by the establishment of a process of counter-action in a remote sympathizing part. With this view we have to recommend, first, once a month the cupping-glasses and scarificator to be applied to the nucha, and a few ounces of blood to be by that means taken away; secondly, dry-cupping to be practiced between or over the scapula every third or fourth day, two cupping-glasses to be allowed to adhere for a quarter of an hour; thirdly, a caustic issue (which is less troublesome and painful in dressing than a seton) to be made in the back of the neck where the seton is usually inserted; and, lastly, once in the week, a moxa, or a blister, not larger than a crown-piece, to be applied to the back of the head, behind the upper part of the ear, where there is space for a succession of four such blisters. If a blister be preferred to a moxa, let it be put on at noon, and it will be ready to be dressed before bed-time, by which means the patient's rest will not be broken, as it generally is, by a blister, however small, applied at bed-time. There is abundant evidence of epilepsy being moderated while a discharge has been maintained, from a sore either accidentally occurring or designedly produced, and being aggravated almost immediately after such discharge has been dried up.

In *epilepsia cerebialis* we wish to promote a more active circulation in the muscular tissue, and in the integuments, especially of the limbs, which is to be done by champoning and frictions, while the head is kept cool and the shower-bath taken daily. Our hope of cure in this form of epilepsy chiefly rests on persevering attention being paid to diet and regimen, and on topical means; yet although our confidence in the use of internal medicines is not so great in this as in the other species of the disease, they are not to be dispensed with, when the functions of the cutaneous, gastro-hepatic, or nervous systems are disordered.

Antimonials are requisite when the skin is inactive, and we have known signal benefit afforded by antimony to those persons who, in advanced life, have laboured under the apoplectic epilepsy, as it has been called. The preparation of antimony which we prefer is James's powder, the pulvis Jacobi veri, and the following is the method of exhibiting it which we recommended a good many years ago,^{*} and which has often been adopted since with advantage. The patient is to begin with a very moderate dose of the powder, not more than two or three grains at bed-time, and to increase the dose by half a grain every night,

^{*} Prichard. [†] Georget, l. c.

^{*} Dublin Hospital Reports, vol. i. p. 315.

till some sensible effect is produced on the skin, stomach, or bowels. Should the stomach at any time be affected with sickness, the dose may be lessened by a grain on the following night. By the addition of a few grains of rhubarb, a larger quantity of James's powder may be administered than the stomach could otherwise bear. If the skin be affected, the dose should not further be increased, but it must be repeated every night for about three weeks; it may then be reduced as it was augmented by half a grain every night, the course occupying a period of at least six weeks. We have known eighteen or twenty grains taken every night for a considerable time without inconvenience, and even when not productive of any sensible perspiration, it has often allayed the heat and restlessness which so often accompany irregular determinations of blood. In very cold weather we have directed the patient to make some addition in point of clothing, but have not confined him to the house even when the snow was on the ground; as we do not consider the system to be more susceptible of catarrhal or rheumatic affections while under the influence of James's powder. To this course of medicine the tepid bath will prove a valuable addition.

If there be any of those scaly affections of the skin to which epileptics are so liable, a draught as follows may be taken:

R Radicis sarsaparillæ concisæ, ʒi.

Radicis glycyrrhizæ concisæ, ʒiii.

Aquæ calcis, uncias x.

Macula in vase clauso, subinde agitans, per horas duodecim, dein cola. Divide in haustus sex. Sumat unum ter quotidie.

When the eruption is not attended with inflammatory heat or itching, the aqua picis liquidæ may be given to the extent of from half a pint to a pint in the day, or as a substitute the pilulæ picisæ.

In indigestion with a loaded tongue, the nitro-muriatic acid may be deserving of a trial, two or three minims of the nitric acid, with four or five of the muriatic, in three ounces of distilled water, may be sucked up through a glass tube or a reed, at least three times a day. Where the breath is heavy, the following powder may be given.

R Pulveris recentis carbonis ligni, gr. xv.

Pulveris rhei, gr. ii.

Pulveris ipecacuanhæ, gr. i. M.

F. pulvis e cyatho vin. aquæ cinnam. bis quotidie sumendus.

If the urine be scanty, with a red sediment, a drachm of Brandish's alkaline solution in water, or an alkaline bitter draught, may be taken every forenoon and evening. We do not object to the occasional use of mercury, but we have never, in this form of epilepsy, willingly given that mineral so as to affect the mouth. If the bowels are confined, one of the following pills may be given at bed-time:

R Extracti aloes,

G. galbani, sing. gr. ii.

Saponis duri, gr. i. M.

Or the following powder, which was the fa-

vourite aperient of a Dutch empiric, who undertook the cure of epilepsy:

R Sulphuris loti, ʒi.

Sulphatis potassæ, gr. x.

Pulveris rhei, gr. v.

Pulv. nucis moschatæ, gr. ii. M.

Lastly, if the nervous system be irritable, the patient desponding and apprehensive, the treatment to be recommended under the head of Epilepsia Nervosa will probably afford relief.

Epilepsia stomachica.—We once had a patient who, in the early part of his life, had been under the care of the celebrated Dr. Cullen. Dr. Cullen kept him in a state of unceasing nausea for a very long time, our impression is for more than a year, and without the slightest relief. It is not so that we would have emetics employed. We conceive that attacks of epilepsy may sometimes be parried by giving emetics at stated periods, and we have been accustomed to prescribe the following emetic in this form of epilepsy, once in the week:

R Pulv. ipecacuanhæ, gr. xv.

Sulph. zinci, gr. v. M.

Two cases of the epilepsia stomachica were successfully treated by giving once a week a calomel bolus at bed-time, and on the following morning a draught containing castor oil and oil of turpentine in the following doses:

R Olei ricini, ʒiii.

Olei terebinthinæ, ʒii.

Mucilaginis acaciæ, ʒiii.

Aquæ menthæ viridis, ʒvi. M.

To the best of our recollection, both patients had a pill of aloes and soap every second day, took bitter medicines, and had their diet regulated with great care, more especially with regard to quantity.

In this form of epilepsy, the bowels ought to be completely emptied, every second day, by means of a dinner pill, and the use of the injection syringe.* The dinner pill may consist of two, three, or four grains of the pilulæ aloes compositæ, or the pilulæ aloes cum myrrha, or of the pilulæ stomachicæ Mesues, now, by an altered name, contributing to the medical fame of Lady Webster, and which owes its efficacy solely to the aloes which it contains, and

* When the bowels refuse to act regularly without the assistance of medicine, which is the case with many persons advancing in life, it is an error to order a purgative every day; the evacuation procured by medicine is generally so complete that a longer time elapses before the bowels fill than after a natural stool, therefore the purgatives resorted to, whether aloetic pill in the evening, or a saline aperient before breakfast, ought to be taken only on each alternate day. Their contents ought to be permitted sufficiently to accumulate before the bowels are again urged to discharge themselves of their load; by this means the cathartic being more completely incorporated with the fecal residuum, irritation and mucous stools will be avoided. If a purgative be taken when the bowels are comparatively empty, more frequent discharges will be obtained, but they will be less consistent and satisfactory; and griping and tenesmus, and perhaps hemorrhoidal irritation, will be the consequence.

to its diffusion among a mass of solid aliment. A pilula ante cibum ought not to contain more than a grain and a half or two grains of aloes, or to be taken every day. The injection may consist of a pint or more of tepid or cold water, with or without two or three drachms of the muriate of soda.

Once every week the bowels ought to be fully evacuated by giving at bed-time a medicine acting upon the liver, stomach, and small and great intestines:

R Hydrarg. submuriatis, gr. ii.
Pulv. ipecacuanhæ, gr. i.
Pulv. rhei, gr. iv.
Extr. aloes, gr. ii. M.

F. pilulæ ii. hora somni sumendæ;
and the following morning before breakfast, a saline aperient draught.

At the same time the patient must have a tonic medicine, twice in the day, containing half an ounce or six drachms of the atramentum Heberdenii, now introduced into the Dublin Pharmacopeia under the designation of *mistura ferri aromatica*, or an ounce of the *mistura ferri composita*, or the following draught:

R Sulph. ferri gr. iii.
Sulph. quininae, gr. i.
Infusi calumbæ, ℥i.
Ac. sulph. dil. m. iii. M.

It is in this species of epilepsy and in nervous epilepsy, that benefit may occasionally be obtained from the *nitras argenti* and *cuprum ammoniatum*. In the cerebral species we have repeatedly tried the former medicine, in the dose of nine or ten grains a day, for a sufficient length of time, without the slightest benefit.

Among the means most likely to improve the state of the digestive system, there is not any which is so uniformly beneficial as change of residence and travelling, and the improvement is often felt for many weeks after a movement. Journeys, in the case of the epileptic, who naturally dislikes to expose his infirmity to strangers, ought to be undertaken shortly after an attack, as a considerable period of time generally elapses before the fit may be expected to return. It would appear from the following observation, made by De Haen, that changes of residence and long journeys have sometimes cured the disease. "*Etiam mutatione domicilii, diuturniore peregrinatione, vitæ genere prorsum permutato, quidam leguntur se etiam ab ipsa gentilitia labe præstitisse immunes.*"

Epilepsy has sometimes arisen from tænia. When this takes place, the treatment will not be attended with much difficulty, as the disease may be removed either by means of rectified oil of turpentine, or by tin in powder given in large doses, and followed by cathartics. We have found in some individuals, that after worms, especially ascarides, have been expelled, so that there was no vestige of them for several weeks, they have reappeared within two months, as if a nidus had been left behind. In such patients, worms may be

permanently destroyed by exhibiting proper anthelmintics before the expected period of recurrence, which may easily be ascertained.

Epilepsia hepatica.—When hepatalgia, biliary colic, icterus, or any other symptom of biliary congestion, precedes or follows an attack of epilepsy, local bleeding, an issue over the region of the liver, and mercurial purgatives will be requisite, and afterwards alternate courses of dilute nitro-muriatic acid and of taraxacum, the latter exhibited as follows:

R Extracti taraxaci, ℥ii.
Extracti gentianæ, gr. x.

Olei cinnam. min. ii. M. et divide in pilulas xii æquales. Sumat tres ter quotidie superbib. haustum decocti taraxaci.

R Taraxaci, ℥ii.
Extr. glycyrrhizæ, ℥ii.

Quæ ferventis quod satis sit ut colentur uncia decem. Coque per horæ tertiam partem et cola. Colaturæ adde supertratis potassæ, ℥i℥. Divide in haustus sex.

Epilepsia nervosa.—The chief indication in this species of epilepsy, after the removal of the exciting cause, is to allay the irritability of the stomach and to strengthen the system. The stomach is ever disturbed, the disturbance evincing itself not in anorexia but in despondency, in irritability of mind, in the *animus*, *nec sponte, varius et mutabilis*, in depression of strength, unrefreshing sleep, and often in that most distressing sensation which has been called "the fidgets;" in palpitation, in acute pain in the mamma, and in the existence of various other symptoms of hysteria. In neither males nor females, is this variety of epilepsy connected with the state of the generative system, unless when the attacks proceed *ex onanism*.

In nervous epilepsy our chief reliance is upon diet, regimen, attention to the state of the bowels, proper regulation of the mind; and on such medicines as valerian, camphor, snake root, and castor. The following draught we have often known to relieve the irritable state of the nerves which attends this species of epilepsy.

R Radicis valerianæ,
Radicis serpentariæ, aa. ℥ii.

Aquæ ferventis, ℥vii. digere per horam, et liquorem frige factum cola. Colaturæ adde

Sp. ammoniæ aromatici, ℥ii.

Tincturæ serpentariæ, ℥vi. M. et divide in haustus sex. Sumat unum meridie et vespere.

Tonics are also applicable to this affection, as cinchona and iron, especially the former when epilepsy is periodic. We have known moderate doses of nitrate of silver given with advantage in aggravated hysteria, and hence, although we have not successfully prescribed it in nervous epilepsy, unless in one instance, there are many cases of this variety of the disease in which it would probably be of great use. Much may be expected from agreeable occupation, variety of scenery, the bracing air

of the sea, and tepid and cold sea-bathing. All kinds of fermented liquor, tea, and also coffee, ought to be given up, together with the use of tobacco, if unhappily the patient should have addicted himself to the use of that poisonous and demoralizing weed.*

Epilepsia uterina.—If the attacks of epilepsy precede the menstrual period or accompany it, the effort of the constitution being imperfect, relief must be sought for in venesection, purgatives, and the antiphlogistic regimen. In the interval between the periods, those emmenagogues must be employed which moderately act upon the intestines, and at the same time give vigour to the circulation; as, for example, pills of myrrh, sulphate of iron, and aloes; or pretty full doses, two or three times in the day, of the carbonate of iron, with a moderate dose, every second night, of the decoctum aloes compositum. The tepid pediluvium, or hip-bath, with friction of the back and limbs at bed-time, more especially just before the menstrual period, may be practised; and in this species of epilepsy also the patient ought to have the benefit of sea-bathing, and frequent changes of residence.

There is a point from which our attention ought never to be withdrawn in the treatment of epilepsy, namely, the exciting cause of the first paroxysm. If the paroxysm have been caused by mental impressions, not only ought the causes of fear, anxiety, and displeasure, to be in as much as possible removed, but endeavours ought to be used to strengthen the mind. If from excess of any kind, then every method of renovation must be employed. If from inanition, proper restoratives must steadily be exhibited. If the disease be periodic and connected with dysmenorrhœa, after evacuations, if they are indicated, anodynes, even in large doses, will be necessary; of which the following will be found one of the most efficacious:

* Tobacco is an enemy to domestic economy and personal cleanliness; it taints the breath permanently, injures the digestion, impairs the intellect, and it even shortens the life of some of its votaries. Cullen says it produces loss of memory before the usual period. Snuff keeps a great many of the females, engaged in lace-making, in this neighbourhood (Newport Pagnell), under the continued influence of hysteria, and gives them an early stamp of age; at thirty a snuff-taker looks as if she were forty years old. It is the sole cause of a variety of dyspepsia, of which we have witnessed a vast number of instances—the symptoms being a painful sensation of a lump at the stomach—of a hard undigested substance pressing, as it were, upon a tender part of the stomach, which sensation is, for the time, relieved by taking food; remarkable depression of spirits, every thing seen through a medium of gloom and distrust; and tremors of the nerves. “Upon an accidental interruption of snuff-taking for a few days the pains do not occur, upon a return to snuff the pains return.”—(*Cullen's Mat. Med.* vol. ii. p. 275.) Chewing tobacco will produce the same affection. Smoking produces anorexia and emaciation. The chief evil, however, in tobacco, taken in any way, is that it leads myriads upon myriads to the habitual use of ardent spirits and opium, and consequently to the ruin of soul, body, and estate.

R Camphoræ, (ope sp. vini rect. in pulv. red.) 3℥.

Extracti hyoscyami, gr. xv.

Extracti opii, gr. iii. M. et divide in pil. xii. æquales.

Of these compound camphor pills two may be taken on the very first accession of pain, two in an hour after, and even a third dose may be taken after a second hour; if relief is not obtained, sometimes a double or even quadruple portion of opium must be given; it being an established point of practice that the pain which attends dysmenorrhœa is to be subdued without loss of time. We apprehend that the efficacy of full doses of camphor on painful menstruation is not so generally known as is desirable.

To propose a regimen of diet, which would apply to every variety of epilepsy, as we have already hinted, would lead to a disproportionate extension of this article. The directions, therefore, which we have given, are of necessity general, and may be departed from should the paroxysms return with unabated frequency. Eminent physicians, as for example Dr. Fothergill, have recommended abstinence from all kinds of animal food and fermented liquors. He tells us that, “In the form of epilepsy, which may be supposed to proceed from disorder of the digestive organs, evidenced in craving appetite, and supported by inattention to diet, laxatives, with a light chalybeate interposed and steadily continued, together with a course of diet consisting of milk, vegetables, fruits, and things prepared from them, and in moderate quantities, seldom fail of removing the disorder.”

In Heberden's Commentaries, we have the following pithy illustration of the importance of diet: “Duo epileptici ab omni cibo animali abstinerunt, et sanati sunt.” And Dr. Abercrombie, no mean authority in this or in any practical point, is of opinion that the only remedies of real efficacy in such cases are purgatives, a strictly vegetable diet, and total abstinence from strong liquors. According to our experience it would not be easy to overrate the importance of diet in epilepsy, at the same time we admit that many changes may be necessary before the full advantage is obtained which diet is capable of yielding;—one rule alone, in our opinion, being established, namely, that food ought ever to be taken in great moderation; in other words, that there is danger in a full meal, however unexceptionable the materials may be of which it consists.

When, in medical works of respectability, we meet with a variety of remedies, many of them possessed of dissimilar qualities, recommended for the cure of the same disease, we must conclude that its species are dissimilar in their nature and require to be treated differently. In examining the anti-epileptic remedies recommended by authors, we may discover four classes, viz. evacuants, tonics, nervines, and emmenagogues: first, those which reduce vascular congestion or action, venæsectio, hirudines, fonticuli, setacea, cauterium,

vesicatoria, irritantia, emetica, purgantia, antimonium, mercurius: secondly, those which invigorate the body and improve the digestion—*aëris et dietæ mutatio, balneum frigidum, cinchona, amara, acida, zincum, argenti nitras, cuprum*: thirdly, medicines which relieve disorders of the nerves—*serpentaria, cardamomum, valeriana, castoreum, moschus, camphora, guaiacum, hyoscyamus, belladonna, stramonium, opium*: fourthly, emmenagogues—*ammonia, galbanum, assaefetida, aloes, ferrum, oleum terebinthinæ, ruta*. A consideration of the foregoing catalogue would justify the division of the subject which in this article has been adopted.

If the necessity of more diligently studying epilepsy, of more carefully attending to its specific differences; if the inapplicability to some cases of epilepsy of the treatment which has succeeded in others, be admitted and acted upon, happier practical results will probably be the consequence. But, lest the reader should suppose that we are too sanguine in this our expectation, he shall have the concurrent testimony of the venerable commentator on Boerhaave produced, to whose authority he will more readily yield: "*Illis observationibus sic collectis et in ordinem digestis, sedulo expendat medicus omnia, et facile detegat regulas agendorum et vitandorum, sed in singulari tantum hujus ægri casu. Nam generales in omnibus epilepticis curandis regulæ haberi nequeunt; quod enim uni prodest, sæpe nocet alteri. Ubi hoc factum, tota difficultas evanuit, nam reliquum est tantum facilis executio bene persensarum rerum. Certum est, medicos, luculenta praxi obrutos, sæpe deficere in cura hujus morbi, cum tempus ipsis non sufficiat, ut singulari ægro tantam curam impendant; verum et doluerunt toties, ægrorum custodes observasse illa, quæ ipsi neglexerant, non sine famæ damno. Credo firmissime, si omnem animi attentionem adhiberent hic medici, quod sanarent plures epilepticos, et levamen adferrent fere omnibus.*"—Sect. 1080.

(*J. Cheyne.*)

EPISTAXIS, (derived from *ἐπι* and *στάξις*, *stillatio*, from *στάζω*, *stillo*), a flow of blood from the nose. This is one of the subdivisions of the natural class of disorders termed hemorrhages, to which article in this work (in order to avoid unnecessary repetition) we refer for a general explanation of the circumstances under which it takes place.

Bleeding from the nose is a physical phenomenon too common and conspicuous to have escaped notice at any period; and from the earliest times its consequences, together with the conditions of the body which have accompanied and preceded it, have been objects of medical observation. The word *epistaxis* has, also, from a very early period, been applied to this affection under whatever circumstances existing; but it is evident that Hippocrates, who has left us several observations on the subject, used its original always to signify an *oozing*, and *αἱμορραγία*, a *rush of blood*: we make, however, no such distinctions.

Of the various hemorrhages, *epistaxis* is the most common; and so often is it attended with salutary effects, that its encouragement and suppression equally require the consideration of the medical practitioner. Its frequency is readily accounted for when we reflect on the structure of the Schneiderian membrane; its extreme tenuity, and the number as well as proportionate size of the ramifications of bloodvessels which traverse it in every direction, forming a complete net-work, with a comparatively smaller portion of interstitial cellular substance and thinner laminæ of membrane enveloping it than is to be found in any other part of the body. The bloodvessels of this membrane being for the most part supplied by the internal maxillary artery, and inosculating with some of the extreme ramifications of the internal carotid, any increased impetus given to the latter, or to the trunk of the former, is less resisted in this part; and, in consequence of the rupture which is very frequently occasioned, an escape of blood is effected, with relief of both these systems of vessels, and, in a very essential manner, to the advantage of the brain.

As in hemorrhages from every other part, it is important to observe that in *epistaxis* there are two opposite conditions of the bloodvessels, induced by corresponding states of the body under which it occurs: in the one the extreme vessels are ruptured by the increased activity of the circulatory system, general and local; in the other, from debility and relaxation their elasticity is destroyed, and, incapable of distention as well as of propelling their contents, their parietes readily give way; or, from the same condition, red blood insinuates itself through the exhalents, instead of the thinner and colourless part of this fluid proper to them. We shall proceed to consider *epistaxis* under these two conditions, adopting the common language of pathologists in applying to the former the term *active* or *entonic*, and to the latter *passive* or *atonic epistaxis*.

Entonic epistaxis occurs occasionally in very young children, most frequently before or about the age of puberty, and in persons of a plethoric or sanguine temperament; the latter are not unfrequently the objects of it until the advances of age effect a change on the constitution, and the balance of power is transferred from the arterial to the venous system. Thus we find in early life that this hemorrhage is almost always from the arteries, and in old persons, when it does occur, that the blood flows from the venous system. The habits and exercises of males render them more liable to *epistaxis* than females; but on the other hand we find in the latter that it is very often vicarious with the suppression of the menstrual discharge, and occasionally occurs with the same periodical exactness. Even in the male sex the influence of habit is often evinced in the occurrence of *epistaxis*, and, after other causes have been removed, it is sometimes with difficulty that its power is resisted.

Local injury, inordinate exercise, exposure to heat, or increased temperature of the atmosphere; hot drinks, stimulating diet, sup-

pressed discharges, either natural or artificial; and all other circumstances which increase the quantity of blood, or the impetus by which it is distributed to the different parts of the head, may occasion the occurrence of epistaxis.

In addition to these causes, it has been frequently preceded by various emotions of mind, terror, anger, and even a single excitement of the imagination; hence, says Mason Good, we may readily trace by what means the philosophers and poets of the eastern world, and even some of those of the western, were led to regard the nose as the seat of mental irritation, the peculiar organ of heat, wrath, and anger; and discover how the same term *אף* (*ap* or *aph*) came to be employed among the Hebrews to signify both the organ and its effect, the nose, and the passion of anger to which it was supposed to give rise.

In some individuals it is probable that there is an extraordinary delicacy of the Schneiderian membrane and its vessels, which renders the latter peculiarly easy of laceration: there appears also to be a degree of correspondence between this expansion and the integuments of the face with which it is continuous, the phenomenon of blushing being often remarkable in persons subject to epistaxis, a circumstance which is doubtless also in great part to be referred to the identity of temperament predisposing to both of these affections.

Excitation of the olfactory nerves, in persons of peculiar irritability of the organ of smell, has occasionally induced epistaxis; an example of this kind has been recorded by Bruyerin, in which it was induced by smelling an apple; and another by Rhodius, in which the odour of a rose appeared to be the exciting cause. Coughing, sneezing, singing, and reading aloud for any length of time, stooping also, and particular postures of the body, have not unfrequently occasioned it. The secretory office of the Schneiderian membrane is liable to material interruptions from the vicissitudes of temperature to which it is necessarily exposed in the act of respiration; and any check by cold to its natural or inordinate secretion will occasionally lead to the rupture of bloodvessels in this part.

The febrile disorders which are attended with determination of blood to the head are often the precursors of epistaxis; and this affection, from the days of Hippocrates, who pronounced it critical, an expression which has been adopted through succeeding ages to the present day, has been welcomed as a salutary effort of nature, either to relieve or bring the disorder to a favourable issue. Some nice distinctions have been drawn, by the great authority just mentioned, of the different indications from the occurrence of epistaxis on different days of the progress of fever; but independently of their being inapplicable to the fevers of this country, more extended experience has shewn that this is to be regarded as only one of an assemblage of symptoms from which our judgment of the issue of such diseases can reasonably be drawn.

Epistaxis has sometimes been observed to

be synchronous with the periodical returns of intermittents, taking place at the accession of the hot stage, when in this, as in other disorders in which fulness of blood in the vessels of the brain has been one of the morbid conditions, the greatest danger of injury to that organ, and its consequences, has been averted by the escape of blood from the nose.

In congestions of blood in other organs of the body, whether of an acute or chronic character, as in the lungs, but particularly in the liver; or in mechanical obstructions to the free course of blood, occasioning its determination to the head, or an impediment to its free circulation in this organ, the same effect has been attended with the same salutary consequences. The suppression of the natural secretions of the body is a frequent cause of epistaxis. We see it occurring very commonly in amenorrhœa; in those diseases in which the secretions of the other mucous or serous membranes are suspended; and not unfrequently when the natural function of the skin has been checked partially or generally. Morgagni has handed down to us the record of an extraordinary, and, as far as we know, a singular instance of the simultaneous occurrence of epistaxis in a number of persons:—it is stated that in the year 1200 there was a great mortality of men in the space of twenty-four hours, in Tuscany and Roman-diola, by a flux of blood from the nostrils; and Morgagni has remarked that Clementini, the historian of Rimini, had noted that in the same year a great number of deaths from hemorrhage had occurred within four-and-twenty hours at Rimini, Ravenna, and in other cities of the Roman province; but from what part of the body is not mentioned. Various conditions of the atmosphere, it is well known, have a powerful effect on the expansive quality of the blood, as well as of other fluids: besides the effect of the stimulus of heat, the *plethora ad molem* is induced by the same cause; it not unfrequently happens that passing from a cold into a heated room occasions this kind of hemorrhage; and a sudden transition in the natural atmosphere occasioned, it is probable, the endemic we have just noticed. The same expansive quality of the blood is evinced by alterations of the atmospheric pressure; and in the ascent of high mountains an early physical consequence has been a flow of blood from the nose, increasing in proportion to the altitude, and succeeded by hemorrhage from the ears and lungs, as well as by other very alarming symptoms. We have an interesting example of this in the enterprising traveller Saussure, on the occasion of his celebrated ascent of Mont Blanc.

The passive or atonic epistaxis takes place only in those extreme states of depression of the vital powers which occasionally occur after the inflammatory stages of fever have passed by, or in such as have been considered of a putrescent tendency, as in the advanced state of eruptive fevers, particularly of malignant small-pox and scarlatina. In cachectic diseases, such as the purpura hemorrhagica, scorbutus, and cer-

tain broken-down states of the constitution, consequent to visceral disease of a chronic kind, particularly that of the liver arising from the long-continued influence of a hot climate, or the habitual intemperate use of spirituous liquors, the atonic epistaxis is occasionally a very troublesome and dangerous symptom.

Instances have been recorded of the loss of almost incredible quantities of blood from the vessels of the nose. Ten, twelve, and upwards of twenty pounds have been known to flow away before the hemorrhage has ceased. "Bartholin mentions a case of forty-eight pounds, Rhodius another of eighteen pounds lost within thirty-six hours; and a respectable writer in the *Leipsic Acta Erudita*, a third, of not less than seventy-five pounds within ten days, which is most probably nearly three times as much as the patient possessed in his entire body at the time the hemorrhage commenced." In the *Ephem. Nat. Curios.* is a case "in which the quantity indeed is not given, probably from the difficulty of taking an account of it, but which continued without cessation for six weeks."*

The active or entonic epistaxis is usually preceded by a sense of weight and fulness in the forehead and face, frequent flushing in the latter, with heat and itching in the nose; a remarkable degree of throbbing is often experienced in the temporal arteries, a ringing in the ears, and sometimes a dull or indistinct sense of hearing; but in many instances no precursory symptom is observed, and the blood issues forth suddenly, with various degrees of force.

Passive or atonic epistaxis occurs, in general, without any preceding indication peculiar to it; and in many instances, particularly in the adynamic states consequent on fevers, it is not unfrequently accompanied with entire insensibility. In the cachectic states of the constitution giving rise to this kind of epistaxis, inordinate and uncontrollable losses of blood from the nose have most commonly taken place, and therefore have been more frequently the objects of attention in advanced than in early life.

Entonic epistaxis is always to be regarded as an indication of the urgent necessity for the system of the bloodvessels of the head to be relieved of a superabundance of this fluid; and so long as this condition lasts, it ought to be encouraged, or at least on no account restrained by direct suppression. It is often observed that the evacuation of a small quantity of blood from the vessels of this organ is the spontaneous cure of a severe headache, or relieves an oppressed state of the brain, dependent on preternatural fulness of its bloodvessels; and it is probable that apoplexies and other dangerous diseases of this organ have not unfrequently been stayed, if not entirely prevented, by this natural method of cure. In advanced life, however advantageous this hemorrhage proves under an immediate threat of such forms of disease, we must bear in mind that it is an indication of an altered condition of the bloodvessels of

the head, which pathologists have observed progressively to increase in the majority of persons after the middle period of life, and that it is often, on this account probably, the precursor of fatal apoplexies, epilepsies, palsies, and other cerebral diseases.

In a practical view we may consider epistaxis, in reference to the condition of the various organs of the body, and the positive disease (if any) with which it is accompanied, in the same light as artificial bloodletting, always remembering the importance and delicacy of the organ to which a determination is already established, or probably would be, if the exit of blood from the ramifications of the vessels supplying the nose were prevented: such diseases and conditions will require their peculiar kinds of treatment, and the avoidance of the exciting causes which produce this particular affection. It occasionally happens, however, that this evacuation is excessive at a single occurrence; or that by its continuance a passive state of the vessels is induced; or sometimes, independently of plethora, the evacuation becomes, by frequent recurrence, habitual, and, if not arrested, would be productive of consequences dangerous to life.

The particular treatment necessary to prevent an excessive or habitual epistaxis of the entonic kind is founded on two principles; 1st, diverting the determination of blood from the vessels of the head to other parts of the body; and, 2dly, the direct application of those means which are calculated to act on the extremities of the vessels themselves; which means consist of astringent substances and mechanical compression.

The former includes the various remedies which are comprehended in the antiphlogistic regimen, those being selected which are adapted to restore the particular function which may in each case have been suspended, and to produce a counterbalancing excitation in a system of vessels at a distance from the already overloaded vessels of the nares and head: hence the use of purgatives is particularly indicated; and in very plethoric habits a combination of such as stimulate the tract of the alvine canal, as well as excite its watery secretions, will be found advantageous.

Bleeding, also, from a vein in the arm or foot, or topical bleeding by leeches applied to the head, or by cupping on the nape of the neck, will be requisite in some cases in which the hemorrhage from the vessels of the nose may have been so small as to point out only the necessity of such an evacuation, but not sufficient to remove the occasion of it, and the symptoms with which it is accompanied. In habitual epistaxis, also, we shall find the necessity often of thus artificially changing the distribution of blood, and, by anticipating the periods of the return of this morbid disposition by proportionate bleeding, may at length be enabled altogether to prevent it.

Emetics have been occasionally of service, and are recommended by Stoll, on the principle of relaxing the capillaries; but unless epistaxis should appear to depend on an inordinate ful-

* Good's Study of Medicine.

ness of the stomach, impeding the due course of the blood in the large vessels, we should be wary in having recourse to them, for the very action they induce is an impediment to the free circulation of blood in the vessels which it is our object to relieve, and has occasionally been the cause of the affection which is to be removed. Sprinkling cold water on the face will often have a powerful effect in the suppression of this kind of hemorrhage, and even immersion of the whole head has been successful when other remedies have failed. A striking instance illustrative of this is recorded by Dr. Darwin, in his *Zoonomia*: the patient was a lady who had epistaxis for several days from a part of the nose to which the attempt to apply mechanical compression had failed, and in whom, from a preternatural sensibility of the pharynx, it was found impossible to stop up the posterior nares: venesection and the other usual remedies had been tried in vain; but by immersion of the head in a pail of water, rendered colder by the liquefaction of some common salt, the hemorrhage was checked, and did not return; but hardness of the pulse continuing, loss of blood from the arm on the following day was resorted to as a requisite precautionary measure.

Dashing cold water on the genitals has sometimes had an instantaneous effect in the suppression of epistaxis. In the same manner, the popular remedy of applying a large key or other piece of cold metal between the clothes and the surface of the back has caused it to cease. The exposure of the face to cold air, the observance of an erect position, with an inclination of the head backwards, cold drinks, and the application of cold water or ice to the nose, will often be sufficient to terminate this hemorrhage.

If these means, however, should fail, the nostril from which the blood issues should be stopped with a piece of lint or other soft substance, so that the retarded blood may coagulate, and thus produce pressure against the ruptured vessel: if this should not succeed, recourse must be had to astringents in preference to methods of compression to be presently described, and which, though perhaps more certain, are extremely disagreeable in their application, and need be resorted to only under urgent circumstances. Astringent applications may be used in the form of an injection with a syringe; or that of powder, carefully blown into the nostril through a quill: the method of inhaling them by an inspiratory action, as commonly advised, is apt to disturb any portion of coagulum that may be already formed, or to increase the excitation of the ruptured vessel itself. A variety of astringent applications have been recommended for the suppression of epistaxis; those most in use are vinegar and water, dilute mixtures of sulphuric acid with water or spirits of wine, spirits of wine alone, tincture of benzoin, solutions of alum, of the metallic salts, &c.; the two last mentioned are chiefly to be relied on, and should always be preferred. Two drachms of alum, or from two scruples to a drachm of sulphate of zinc, dissolved in half-a-

pint of distilled water, or the solution of the acetate of zinc of the Edinburgh Pharmacopœia, or a drachm and a half of the muriated tincture of iron, diluted with six ounces of water, will be suitable injections for this purpose: the common solution, also, of the acetate of lead, or the same salt in a much less diluted state, may also be used for the same purpose, after which a piece of lint, imbued with whichever of the solutions may have been preferred, should be passed up the nostril with a probe, or some such instrument, so that firm compression may be effected.

The powders to be used in the manner we have already stated, ought to be finely levigated; but even in this state the irritation they are apt to excite may be productive of consequences which would more than counterbalance the advantages to be expected from their astringent quality. The sulphate of alum and powder of galls have been usually preferred; a powerful styptic has also been found in charcoal, either used in the form of powder, or mixed with water and applied as a paste on a tent of lint. An instance of the successful use of the powder of gum acacia blown into the nostril in a case of epistaxis which had continued for two days, and had resisted the other means generally adopted, has been transcribed from Hufeland's *Journal* into the 27th volume of the *Medical Repository*. As this substance is not only free from the objection we have mentioned to astringent powders, but congenial to the sensibility of the Schneiderian membrane, and probably produces its good effect simply by increasing the tenacity and adhesive quality of the blood on its issue from the extremity of the bleeding vessel, it appears to us that in some cases it may be an eligible application.

Should the practitioner be baffled in his attempts with the means above suggested, or should the unsuccessful use of one astringent give little promise of advantage from another, direct compression may be made by passing a long piece of catgut from the anterior aperture of the nostril which is the source of the hemorrhage, so far into the pharynx, that by a pair of forceps it may be drawn into the mouth, in order that a piece of cotton or lint may be attached to it, of sufficient thickness to press against the parietes of the canal when the catgut is again retracted: this being done, it is to be separated from the lint or cotton, which is allowed to remain in the canal until further means shall have had the effect of suppressing the hemorrhagic tendency. Such is the method generally recommended by surgical writers, but the irritation excited on putting it into practice, and, when effected, the aversion expressed by patients to its endurance, are so great, that whatever the danger may be, they will rarely submit to or suffer its continuance for a sufficient length of time; and it must be acknowledged that there is some hazard that its removal may prove a fresh cause of excitement. A great surgical authority (Mr. Abernethy), with his accustomed humour, has told us that he knew that such a method could be adopted, for he had seen it done; but that whenever he had tried to do it

he always failed, finding an obstacle in the excessive irritation produced in the muscles of the pharynx: but the same authority has observed that he had never seen an instance of epistaxis which could not be suppressed, (and that he had seen a great many instances,) by the introduction of a cylindrical plug of lint through the anterior nares, made sufficiently large to fill the tubular part of the nostril, being first wetted and wound round a probe, so as to give it the form of a bougie, long enough to allow it to be passed along the floor of the nose from the anterior to the posterior aperture, but not into the throat; the probe being withdrawn when the lint has been thus disposed of. This plug should be allowed to remain in three or four days, while the proper means are taken to remove the causes of the occurrence of the hemorrhage.

The after treatment, which is usually of more importance than the immediate suppression of nasal hemorrhage, (for the latter will frequently cease as soon as it is desirable that it should do so,) consists in the pursuance of the antiphlogistic regimen to a degree commensurate with the urgency of the general symptoms and state of the body. It is necessary to consider how far it may be safe to regard the recurrence of an attack as the salutary consequence of the impeded function of a particular organ, or other coexistent disease; and how far, also, it may be reasonable to anticipate the practicability of the restoration of the one or the cure of the other, on which the hemorrhage may depend, without the hazard of a further loss of blood, if it should happen, exceeding the necessity of the system, or being otherwise disadvantageous to the circumstances of the patient.

We deem it superfluous to enter into a detail of the antiphlogistic means to be adopted; the general condition of the system affording the best indication of the extent of reduction which may be necessary. It will be evident that the causes which excite the attacks in the first instance must be avoided as those likely to promote their recurrence. The observations already made as to artificial bloodletting, purgatives, and emetics, will also be applicable to the state we are now considering. It may nevertheless be necessary to diminish the action of the heart and arteries further than it would be prudent to attempt by greater abstraction of blood, as well as to oppose the reactive tendency which may exist when this remedy has been adopted. In digitalis, or nauseating doses of tartrate of antimony, the suitable means will be found: one or both of these may be combined with the common diaphoretic saline draught and nitre, or other excitants of the skin and kidneys.

When this hemorrhage, either from long continuance or habit, has induced an atonic state of the bloodvessels, and a disposition to its inordinate or frequent recurrence is manifested, the internal use of diluted sulphuric acid, or superacetate of lead, may be advantageously had recourse to; and whether the hemorrhage be combined with an entonic or atonic condition of the body, if it have been excessive, or there should be reason to apprehend that it may prove so, experience has shewn that either of

these astringents will be a powerful adjuvant whether to the antiphlogistic or tonic plan of treatment, whichever may be directed to establish the contractility required in the ruptured end of the bleeding vessel from which the effusion may have taken place. This consideration leads us to notice a remedy,—the ergot of rye, which, from its powerful effect of exciting the natural action of the uterus, has been applied to a corresponding condition of the bloodvessels of that organ productive of hemorrhage, and, as it appears, with the desired effect: on the same principle it has lately been used in epistaxis;* and as it was followed by its cessation, further experience may determine it to be a valuable remedy in this as well as in other kinds of hemorrhage in which the bleeding vessels are reduced to an atonic state. Our present experience of it, however, in cases of epistaxis is too limited to enable us to decide on its eligibility.

In passive or atonic hemorrhage it is scarcely necessary to observe that those means which constitute the antiphlogistic regimen are inadmissible. The general treatment must be adapted to the disease, whatever it may be, which exists with this affection; and on some occasions, when the hemorrhage is excessive and exhausting, powerful stimuli will be required: a large dose of laudanum, with carbonate of ammonia and camphor mixture, may be given with advantage under such circumstances; brandy and water, brandy-gruel, wine, strong animal soups, and jellies will also be necessary to recruit the exhausted strength of a patient, weakened as he must be by the continued or repeated drain of this vital fluid, under circumstances of disease in which debility is a fearful, and in many instances an irremediable condition.

The local treatment consists of the application of astringents and the use of compression or stoppage by the insertion of lint or cotton, as advised in the local treatment of entonic hemorrhage; and must be immediately adopted, unless in some peculiar states of the bloodvessels of the brain, in which it is possible that the balance of advantages may preponderate in favour of a slight evacuation of blood from the vessels of the nose, even though they should be in a passive or atonic state: but as this occurs in the advanced stages of continued and eruptive fevers, or purpura hemorrhagica, or of scorbutus, accompanied with every other symptom of exhaustion, the oozing of blood should be restrained as soon as possible. It too often happens, however, under such circumstances, that the work of death is already begun, and that the arrest of the hemorrhage by mechanical and not vital power, proves but a feeble obstacle to its completion.

(W. Kerr.)

ERETHISMUS MERCURIALIS, mercurial erethism. The word *erethismus*, (from *ἐρεθίζω*, to excite or irritate,) is obviously a generic term which may be applied to any kind of morbid sensibility or irritability; but

* Med. Chir. Rev. July 1831.

it has hitherto been almost exclusively confined to that species of erethism which sometimes arises from the use of mercury, and to which the appropriate name of *erethismus mercurialis* was given by the late scientific John Pearson, to whom we are indebted for the first notice of the disease. Prior to the period at which that distinguished surgeon was elected to the charge of the Lock Hospital, a year seldom elapsed without the occurrence of two or three sudden deaths, without any assignable cause, among the patients who were undergoing a mercurial course. These were, in truth, cases of mercurial erethism, the nature of which was not then understood. Mr. Pearson has well described the disease as characterized "by great depression of strength; a sense of anxiety about the præcordia; irregular action of the heart; frequent sighing; trembling, partial or universal; a small, quick, and sometimes intermitting pulse; occasional vomiting; a pale, contracted countenance; a sense of coldness: but the tongue, (Mr. Pearson adds,) is seldom furred, nor are the vital or natural functions much disordered." The affection appears to arise from mercury acting as a poison. So great is the danger attending this affection in its severer form, that any sudden or violent exertion may prove immediately fatal. Happily, however, its first appearance may be readily detected, and, by prompt measures, effectually removed. A tremulous motion of the tongue, a slight trembling in the limbs, or a sense of fluttering within the chest, are among the earliest indications of its approach. The pulse becomes feeble, hurried, and irregular, sometimes intermitting for several seconds, and then beating with great rapidity. On applying the hand to the left side of the chest, the heart will be found to act with extreme irregularity.

This peculiar irritation may arise from the administration of mercury in any form; and may occur during any period of a mercurial course, though most commonly at its commencement. The exact circumstances which favour its occurrence in the particular individuals attacked have not hitherto been ascertained. The writer of this article, while resident medical officer of the Lock Hospital, has seen it produced by the inunction of a single drachm of mercurial ointment, and reproduced, in the same individual, after the discontinuance of the medicine for a whole month, by three frictions, each consisting of only one drachm of the ointment. It is remarkable, however, that in the greater number of instances, a full and adequate course of mercury has been afterwards borne, without any recurrence of erethismus, by the very persons who had suffered from it during the commencement of the course.

The treatment of the mercurial erethismus is as simple as it is effectual. *The open air is the grand antidote.* As soon as the slightest intimation of the disease is perceived, the patient should be carried into the open air, with as little exertion to himself as possible, and there he should remain as long as may be

practicable. To use Mr. Pearson's words, "he should *live* there." Mercury, in every form, must be immediately discontinued, and a mercurial atmosphere carefully shunned. If inunction have been used, the skin should be thoroughly cleansed from any adhering ointment. The subcarbonate of ammonia, either with or without camphor, is an important auxiliary, and may be given in rather full doses, at moderate intervals, until the circulation becomes more steady, and the general power of the system revives. It is an important and encouraging fact, that from the time at which this treatment was adopted by Mr. Pearson, not a single death occurred from erethismus at the Lock Hospital.

After an attack of mercurial erethism, great circumspection will be needful both as to the time of recommencing, and the mode of conducting, the mercurial course. In the slighter cases, the disease entirely subsides in five or six days, and even in the severer forms the mercurial treatment may often be safely resumed within a fortnight. Still the most watchful care must attend every remaining step of the course.

The reader may consult with advantage Pearson's Principles of Surgery, and the observations, by the same author, of the different articles on the *Materia Medica* which have been employed in the cure of *Lues Venerea*.

(T. H. Burder.)

ERYSIPELAS. This term is derived, according to some authors, from *ἐρύω*, to draw, and *πέλας*, adjoining; implying that the disease has a tendency to spread to the adjoining portions of skin. Various other derivations have been suggested, but that now adopted appears to be the more correct. It was termed by the Greeks *ερυσίπελας*, by the Romans *Ignis Sacer*, and is known in popular language by the name of *the Rose*, from the colour of the skin, and by that of *St. Anthony's fire*, from the burning heat with which it is accompanied.

Erysipelas may be defined, inflammation of the skin, either alone, or combined with that of the subjacent cellular tissue; generally, though not always, accompanied with vesicular eruption, the local affection being attended by symptomatic fever.

The confusion and contradiction which have existed among practical writers respecting the nature of erysipelas, have in some measure arisen from attempts to found a correct classification of its varieties on some unimportant circumstances in its progress. For example, Cullen places erythema and erysipelas, which are certainly only modifications of the same disease, under different orders. He classed the former among the Phlegmasia, the latter among the Exanthemata or rashes. It is evident, however, that he was aware of their identity, as he laid down their diagnosis with great accuracy in the following passage. "When the disease is an affection of the skin alone, and very little of the whole system, or when the affection of the system is only symptomatical of the external inflammation, I shall give the disease the name

of erythema; but when the external inflammation is an exanthema, and symptomatic of an affection of the whole system, I shall then name the disease erysipelas.* If Cullen intended to apply the characters of his order Exanthemata to erysipelas, it must be observed that it does not correspond in its most important features with this order.

Willan† and Bateman‡ classified erythema and erysipelas according to their occasional external characters. Thus erythema is placed among the Exanthemata, and erysipelas among the Bullæ. This classification would be less exceptionable were vesication an invariable accompaniment of the cutaneous inflammation; but when we consider the occasional absence of this symptom in erysipelas, it is clear that any nosological arrangement founded on an appearance which is not invariably observed, can only lead to confusion and misapprehension.

J. P. Frank§ has adopted Cullen's classification as to erysipelas, but includes erythema among the Impetigines, while Rayer|| after grouping together erythema and erysipelas, places them among the Exanthemata. Mr. Lawrence¶ considers erysipelas to be inflammation of the skin, but that like other inflammations it varies in degree. When it affects the surface of the skin, which is red, not sensibly swollen, and without vesication, it constitutes erythema. When the inflammation is more violent, so as to produce swelling of the skin, or in still more severe cases, when the cellular and adipose membrane, as well as the skin, become inflamed, he designates the disease erysipelas.

Varieties of erysipelas.—The various forms of erysipelas depend on the degree of the local inflammation, the type of the accompanying fever, and on particular circumstances with which the case may be complicated. A full account of the varieties of this disease will be found in the article ERYTHEMA.

Various divisions of erysipelas have been proposed. Some writers, as Burserius, have founded distinctions on its supposed causes. This author divides it into three species: 1. *primary* or *idiopathic*; that is, arising spontaneously from an internal cause, not preceded by any other disease; 2. *symptomatic* or *secondary*, supervening on another disease, by which its progress is influenced; 3. *accidental*, when it is excited by some obvious external cause.

Others, again, have divided the disease into *idiopathic*, (from an internal cause,) and *traumatic*, (from an external wound.) Later writers have introduced subdivisions from differences in the degree of local inflammation. This seems to have been the ground of Willan's and Bateman's classification: viz. 1. *phlegmonous*; 2. *œdematous*; 3. *gangrenous*; to which they add, 4. *erratic*, (migratory.)

Another distinction has been made, according as the disease appears on different regions of the body, viz., *erysipelas of the face and head, of the trunk, and of the extremities*.

We shall describe three forms or varieties: 1. *simple erysipelas*; 2. *phlegmonous erysipelas*; 3. *œdematous erysipelas*; and afterwards point out some differences depending on its situation on the several regions of the body.

1. *Simple erysipelas.*—In this, which is the mildest form of the disease, the inflammation is confined to the skin, which is hot, smooth, red, and shining; the colour varying from a bright scarlet to the more deep rosy or livid tint.

The swelling is either so inconsiderable as to be scarcely perceptible, or, when the inflammation is in a greater degree, an evident tumefaction is felt on passing the finger over the inflamed surface. When the inflammatory action is still more considerable, effusion takes place into the subjacent cellular tissue; and when this happens, the swelling is proportionably increased. The accompanying pain, which varies according to the intensity of the local disorder, is of a pungent burning kind, very different from the throbbing or pulsatile pain of phlegmon. About the third or fourth day after the appearance of the disease, vesications form on different parts of the inflamed skin, after which there is a sensible diminution of the local suffering. The vesicles are sometimes small and numerous; occasionally they are of a larger size, and in a day or two either break and discharge their contents, or the fluid dries into hard yellow crusts, which fall off, leaving the subjacent skin sound, or sometimes abraded. In very mild cases the local symptoms disappear without vesication or even desquamation of the cuticle; more generally, however, when the inflammation ceases, the cuticle becomes detached and falls off in successive portions. Although in by far the greater number of cases the disease is thus terminated, in some instances its disappearance from one part of the skin, more particularly if sudden, is followed by its appearance on some other part. When erysipelas shews this tendency to metastasis or translation, it constitutes the *erratic* form described by Willan and other authors. In such instances it is important to watch the condition of the internal organs, more particularly if the recession of the erysipelatous inflammation be followed by symptoms which indicate visceral disease.

Swediaur* gives the case of a robust plethoric man, 55 years of age, who had for many years laboured under paroxysms of gout, which returned at stated periods. He had been free from his gouty attack for a longer period of time than usual. The eyelids became suddenly swollen; two days after, the œdema disappeared from the palpebræ; he then complained of pain in the throat and difficulty in swallowing. This was soon removed by the use of gargles, when the œdema of the eyelids returned: in a few days afterwards the fingers of the right hand became in succession red and swollen, and subsequently ulcerated. The man

¶ Med. Chir. Trans. vol. 14.

* Nov. Nos. Meth. Syst. vol. ii.

then recovered. After the lapse of some months the disease returned, and assuming the same migratory course, fixed in the feet, where it produced ulceration, on the healing of which the patient's health was completely restored.

Frank* relates the history of a woman in whom erysipelas migrated from the face to the feet, thence to the hip, and afterwards re-appeared on the face. After it disappeared from the face, the intestines became affected; soon afterwards she was seized with disease successively in the chest and in the brain.

Willan gives the only case of erratic erysipelas which had in his experience proved fatal. A labouring man, aged 44, after much fatigue and exposure to cold, became affected with cough, shortness of breath, and febrile symptoms. Five days afterwards an erysipelatous patch appeared on his left shoulder, and another on the left leg. On the seventh day, similar patches appeared above and below the knees. On the eighth day the eyelids became tumid and red. About this time the other swellings assumed a livid hue, the febrile symptoms increased, and were attended with deafness and coma. On the ninth day the tumour of the right eye extended to the temple, upon which small phlyctenæ soon after formed. On the eleventh and twelfth the patient seemed totally insensible; his pulse became feeble and irregular, and he died on the following day.†

2. *Phlegmonous erysipelas*.—In this form the inflammation affects the skin and the subjacent cellular and adipose tissues, and generally terminates in suppuration, and even sloughing of the affected parts. It generally occurs in young plethoric persons; those in more advanced life, however, are not unfrequently the subjects of it, though its progress is more rapid, and its duration shorter, in young than in elderly people.

Phlegmonous erysipelas appears more frequently on the extremities than on any other part of the body. The fever with which it is accompanied is of the inflammatory character; and occasionally symptoms of gastric disturbance arise, either at the beginning or during its progress. The redness of the skin is of a deep tint, and, as in other forms of erysipelas, disappears on pressure. The pain is severe, and accompanied with a sensation of burning heat, while, in consequence of the effusion which takes place into the subcutaneous cellular membrane, the affected parts communicate a peculiar feeling, which has been expressed by the term *brawny*.

When the disease has gone on for four or five days, vesications appear, and go through the same changes as in simple erysipelas; or sometimes, instead of this process, desquamation of the cuticle takes place. The redness then declines, the skin assumes a yellow tinge, the swelling and febrile symptoms gradually subside, and the disease may thus end in resolution. This favourable termination is by no means common. Phlegmonous erysipelas more

commonly ends in suppuration, and even in gangrene, the purulent matter in the former case being either confined in small abscesses, or diffused in the cellular membrane.

When gangrene takes place, the cellular membrane becomes completely disorganized, and, according to the description of Mr. Lawrence, appears like a dirty spongy substance filled with turbid fluid; then losing its vitality altogether, it is converted into more or less considerable fibrous shreds of various size and figure, which come away, soaked with matter like a sponge; while the integuments, being deprived of their vascular supply, become livid, and often lose their vitality. When these changes take place, the tension of the previous inflammatory stage is succeeded by a peculiar softness; the sensation thus imparted has been compared to that excited by a quagmire or morass, and hence the term *boggy* has been given to it.

When an entire limb is affected with phlegmonous erysipelas, the inflammation and subsequent disorganization of the cellular tissue is not confined to that portion which is immediately under the skin, but extends to the intermuscular stratum. Should the patient survive such an attack, the skin, fascia, muscles, tendons, and bones, as stated by Mr. Lawrence, are so agglutinated and fixed, after the extensive destruction of the connecting cellular tissue, that the motions of the part are permanently and seriously impaired.

Various morbid appearances in the internal organs have been discovered in fatal cases of phlegmonous erysipelas. These organic inflammations, which were evidently the more immediate cause of death, have been often unaccompanied by symptoms by which their existence during life could be ascertained.

3. *Œdematous erysipelas*.—This species, which may be said to be intermediate between the simple and phlegmonous, is observed chiefly in persons of impaired constitution, or in those who have a tendency to dropsical effusion. The skin, which is of a pale red colour, inclining to a yellowish brown, is smooth and shining, but less hot and painful than in the other forms. The inflammation is of the subacute kind, and gives rise to serous effusion; the swelling extends slowly and gradually, leaving the impression of the finger as in anasarca, from which circumstance this form has received its distinctive appellation. In the more acute cases thin purulent matter is often mixed with the serosity. Vesications are less commonly observed in œdematous erysipelas, and the vesicles are smaller, less elevated, and more numerous than in either the simple or phlegmonous forms.

It is very liable in some situations to terminate in gangrene; this is announced by the redness changing to a livid hue, and by the cessation of pain. Hence, when erysipelas appears on the genital organs, or on dropsical limbs, when the skin is much distended, or when punctures have been made with the intention of allowing the fluid to drain off, gangrene frequently supervenes. When, therefore,

* De cur. Hom. Morbis, vol. ii.

† Willan on Cutaneous Diseases.

it is deemed advisable to puncture dropsical parts, the best mode of preventing such consequences is to insert a fine couching needle under the skin at short distances. This mode has been found preferable to making small incisions with the lancet, in so far as it is seldom followed by erysipelas.

4. We shall next advert to some differences in the local and general symptoms of erysipelas, depending in some measure on the situation of the part on which it appears. It is a matter of daily observation, that when erysipelas occurs on the extremities, it is less severe than when it appears on the trunk: it is almost invariably confined to one limb, and seldom attended with danger, unless, from its proximity to any of the larger joints, articular inflammation arises, which may terminate in effusion, or some other consequence of synovial inflammation.

In no region of the body is erysipelas more formidable and dangerous than on the face and scalp. The severity arises chiefly from the inflammation of the brain or its membranes, which almost invariably supervenes. Erysipelas of the face or scalp (to which the name *sideratio* has been given) is preceded by two or three days' smart febrile indisposition. The redness appears on some part of the face, from which it gradually spreads: it is sometimes confined entirely to the side of the face in which it first appeared; but more generally it is diffused over the whole face, forehead, and scalp; and occasionally creeping down the neck, extends to the shoulders and trunk. In other cases it first appears around some slight wound, such as those made by leeches or by the cupping scarificator, or around the margin of a blister: sometimes it succeeds to an external injury of a more severe kind, a lacerated or contused wound of the scalp. As the disease advances, the face, and more particularly the eyelids, become swollen; the vessels of the head pulsate strongly; delirium, at first transient, but afterwards constant, comes on, succeeded by drowsiness or coma; vesications or desquamation of the cuticle take place about the fourth day, after which the local and general symptoms abate: in more severe cases, however, the symptoms in the brain increase; the delirium increases; the patient either becomes furious, or falls into a state of perfect insensibility, and after lingering till the tenth or twelfth day, dies from the effects of cerebral inflammation. In other instances, in which the brain affection has been less intense, external abscesses form, most frequently on the eyelids: occasionally the matter becomes diffused in the cellular tissue of the scalp, or when the inflammation has terminated in gangrene, sloughing of this membrane takes place, the pericranium being often detached, to some extent, from the cranial bones. The parotid and cervical glands become inflamed in severe cases, and not unfrequently abscesses form in the cellular tissue in which they are embedded.

It is necessary to notice a form of pharyngeal inflammation which has been observed when erysipelas is prevalent at certain seasons, or appears in some localities as an epidemic.

Some have described this affection as erysipelatous inflammation of the throat; and although this term conveys a pretty accurate idea of the nature of the disease, we think the application of the term erysipelas to inflammation of mucous membranes incorrect, inasmuch as the term ought to be restricted to cutaneous inflammation. In the affection to which we allude, though there is fever, and pain in the throat, especially on deglutition, there is little swelling, but general redness of the fauces.

Dr. Stevenson,* who has given a condensed but good description of the disease as it appeared at Arbroath, states that in some cases the inflammation was confined to the fauces; in a few, however, it spread to the larynx, producing symptoms very like idiopathic croup; in others it extended to the pharynx and oesophagus, when he remarked that though fluids and solids could be partially swallowed without much apparent difficulty, after a few seconds the patient felt pain in the gullet, followed by inverted action and partial or complete rejection of the food. In the more protracted cases swelling and suppuration of the cervical glands took place. It has been also remarked, that while in some individuals this affection was confined to the throat, in others, after commencing in the fauces, the inflammation spread to the face and head, giving rise to erysipelas when the cutaneous structure became affected. This circumstance, and the occurrence of this affection of the throat at the time when erysipelas was prevalent, besides the fact that in erysipelas of the face the inflammation frequently spreads from the face to the mucous cavities of the nose and mouth, shew that the diseases are essentially the same, modified only by the difference of the structure in which they occur.

In the London Fever Hospital, as well as in general hospitals, erysipelas is by no means uncommon. Of protracted cases of malignant fever especially, it is a frequent and dangerous consequence; and we have occasionally observed that the inflammation commenced and was confined entirely to the throat: more generally, however, the inflammation, after beginning in the throat, has spread from the mouth to the cheek and face, or through the nostrils to the nose, and thus erysipelas has been propagated to the face and head. When this form of pharyngeal inflammation is confined to the throat, it appears to us to be in some measure allied to the *Diphtherite* of which Bretonneau has given an excellent description. There is, however, no pellicular or membranous exudation, which forms the characteristic distinction of diphtherite—indeed, in several fatal cases, in which this pharyngeal inflammation was combined with erysipelas of the face and head, we have found scarcely any traces of the previous existence of inflammation. There cannot, however, be the slightest doubt of the inflammatory nature of the affection we are now describing, though it does not induce any of the morbid products of inflammation.

* Med. Chir. Trans. of Edin. vol. ii.

Although erysipelas seldom appears before the age of puberty, a severe form of it occasionally occurs in infants a few days after birth, sometimes, however, so late as the eighth or ninth week. Infantile erysipelas, as it is termed, is more common in lying-in hospitals than in private practice. It appears first on the lower part of the abdomen or on the genital organs, and gradually extends down the thighs. The skin is not much swollen, but becomes hard and of a dark red or livid colour: vesication and gangrene follow, and the genitals are not unfrequently entirely destroyed. This form of erysipelas generally terminates fatally. A milder species is occasionally observed in the hands and feet, and sometimes about the neck or face. It generally lasts twelve or fourteen days, and then disappears, though sometimes it terminates by suppuration and the formation of small abscesses.

Nature of erysipelas.—Great diversity of opinion has prevailed as to the true pathology of this disease, and consequently as to the mode of treatment to be pursued. The ancients attributed this, in common with every acute disease, to supposed acrimony of the fluids, which idea was apparently strengthened by the vesication which frequently arises in its progress, as well as its occasional termination in effusion, suppuration, or gangrene. The more rational and consistent views of pathology which the doctrines of solidism introduced, have tended in a great measure to throw discredit on the application of the humoral pathology to erysipelas.

From the history and progress of the disease which we have laid before the reader, the acute nature of erysipelas is apparent. We have seen in the local symptoms the most satisfactory proofs of inflammatory action—redness, heat, pain, and swelling: moreover, if we trace its termination in resolution, effusion, suppuration, and gangrene, the conclusion, according to the soundest principles of pathology, is, that wherever erysipelas appears, there is inflammation of the skin, or of the cutaneous and cellular tissue combined.

If we advert to the general or constitutional symptoms, we find they are exactly proportionate to the extent and intensity of the local affection. Again, we have stated, that in the more severe instances of phlegmonous erysipelas, inflammations of internal organs arise; and if the opinion of M. Ribes be correct, that in erysipelas the internal tunic of the veins and arteries of the integuments is inflamed, and that these vessels occasionally contain pus, we have a further corroboration of the inflammatory nature of the disease. It must, however, be kept in mind, that in one case the cutaneous inflammation may be so trivial as scarcely to produce disturbance in the system; in a second, the local symptoms are more severe, and accompanied with corresponding general excitement; in a third, the local symptoms may be acute, but the powers of the patient may be feeble, or the fever with which they are accompanied, of the low or typhoid form. To

us it appears that the conflicting and very opposite opinions which have been and still are entertained of the nature of erysipelas, would be brought to harmonize, if more attention were paid to the prevailing character or type of the disease, the duration or stage when the practitioner is consulted, the age and individual peculiarities of the patient, and the treatment which has been adopted in the early commencement of the disease.

Though in the majority of instances the symptomatic fever is acute, such as always accompanies inflammatory diseases, yet, in many cases, especially in the aged, in persons addicted to intemperance, in those who are the subjects of organic disease—or when erysipelatous inflammation supervenes on protracted convalescence—moreover, at certain seasons or in particular years,—the local symptoms are attended with a low form of fever, which does not well bear active depletion, the modified antiphlogistic treatment being more successful. Indeed, as the disease advances, more generous diet, and in some instances the employment of stimulants are found necessary.

This low symptomatic fever, however, is only occasionally observed; it forms the exception, not the rule, and leads to the practical inference, that this disease cannot be successfully treated upon one invariable principle; that the various circumstances pointed out should be kept in mind before we decide on its precise nature, and the line of treatment to be pursued. If the practitioner acts with the caution suggested, keeping in mind the principles we have laid down, he will seldom fail to form a proper judgment of any case he may be called on to treat. In fact, such variations of type are not peculiar to erysipelas; they are constantly observed in all febrile diseases. Epidemic fever, small-pox, measles, and scarlet-fever vary much in their symptoms and general aspect at different times.

Causes.—It is in most instances difficult to trace the exciting causes of erysipelas. When it occurs after local injury, we have at once a probable reason for the surrounding integuments assuming inflammatory action: still, as erysipelatous inflammation does not succeed to external injury in every case, some other circumstances must concur to induce it in those instances in which it succeeds to accidents or operations. There is in many persons a disposition to inflammation of the skin on the most trivial irritation; in such there is, no doubt, some peculiarity in the vascular system of the integuments; so that any causes which excite the circulation either generally or locally, may induce erysipelas.

It is frequently dependent on gastric derangement, and from the intimate sympathy which exists between the skin and mucous membranes, irritation of the stomach and bowels may become not only a predisposing but an exciting cause, especially when there is susceptibility to this disease. On the other hand, the irritation in the skin during attacks of erysipelas frequently induces sympathetic disorder of the biliary and gastric

system. Hence the origin of the term *bilious*, applied to those cases in which the erysipelatous inflammation is accompanied with gastric derangement.

Some persons, more particularly elderly persons of a cachectic habit, and females about the period of the cessation of the catamenia, are liable to periodic attacks of erysipelas, which are generally preceded or accompanied by symptoms of derangement in the stomach and bowels, but seldom with fever. When the erysipelatous inflammation in such cases appears on the extremities, it sometimes induces thickening of the skin, and occasionally superficial ulceration, which proves troublesome and tedious to heal.

Besides the origin of erysipelas from causes originating within the system itself, it appears to prevail more at certain seasons than at others. The spring and autumn are the periods of the year when it is most prevalent; it occasionally assumes an epidemic or endemic character, from which circumstance it has been supposed to be engendered by a particular condition of the air, or at all events to be materially influenced by atmospheric causes.

There have been at various times visitations of epidemic erysipelas. It appeared at Toulouse in 1716, when from its great fatality it was compared to the plague. De Haen,* Bartholine,† Silvius de la Boe,‡ besides other writers, describe an epidemic erysipelatous fever, which was accompanied with inflammation in the stomach and duodenum.

Bromfield§ mentions erysipelas of the head, which was epidemic for two years. Evacuations generally proving fatal, it was treated by bark and cordials.

When erysipelas is epidemic, it is severe and often fatal. The inmates of crowded establishments, more especially of hospitals for the reception of the sick, situated in the vicinity of those districts in which it is prevalent, are particularly liable to its attacks; and so long as the epidemic prevails, the slightest causes are often sufficient to produce the disease. It is, however, more likely to occur in those persons whose health has been previously broken by protracted diseases. It is also a frequent concomitant or consequence of fever treated in hospitals, though it rarely occurs among fever patients in the better class of society. When hospital erysipelas once appears in the wards, it is most difficult to prevent its spreading; and although it succeeds to operations, wounds, or injuries, or supervenes on some slight irritation of the skin, as, for instance, around the incision made by the lancet in venesection, or by the cupping scarificator, or appears around the leech-bites, or the margin of a blistered surface, it frequently arises spontaneously on various regions of the body, in patients whose local disease is not accompanied by an external wound. It has

been sometimes so formidable in hospitals, as to render it necessary to shut up particular wards, and even to delay the performance of surgical operations, the most unimportant being at such times followed by severe and often fatal erysipelatous inflammations.

When erysipelas succeeds to external injuries, such as accidents or operations, it may often be traced to imprudence on the part of the patient, more particularly to errors of diet, or to mental or bodily excitement. In many instances the occurrence of erysipelas after operations or injuries, is the result of unskilful local or general treatment on the part of the surgeon, and more particularly of the neglect of the cooling antiphlogistic treatment during the constitutional excitement which generally follows capital operations.

Erysipelas may also arise from local irritation, long-continued or undue pressure, improper exercise of an inflamed part, or the application of stimulants or irritants to sound or ulcerated parts.

Well authenticated facts warrant the conclusion that under certain circumstances erysipelas may spread by contagion; rarely, however, in clean and properly ventilated dwellings. It is in vain to urge the fact of the disease spreading from person to person, as its propagation might be the consequence of exposure to the same causes; but when we find persons who, after becoming infected apparently from attendance on erysipelatous patients, remove as soon as they become ill to another residence at some distance, and communicate the disease to the family, the irresistible conclusion is, that erysipelas in such cases has been communicated by contagion.

Ample proofs of the truth of this opinion will be found on reference to the papers of Dr. Wells,* Dr. Stevenson,† Dr. Gibson,‡ Mr. Arnot,§ Mr. Lawrence,|| and others. A short abstract of the most striking facts is subjoined. Dr. Wells was called to attend an elderly man with erysipelas of the face, which proved fatal. His wife was seized with it a few days after his decease, and also died. Five weeks after, the landlady who resided in the same house had erysipelas of the face, but recovered. The nurse, who attended the landlady, was attacked with the same disease, and died in the parish workhouse. The nephew of the person first attacked was taken with erysipelas shortly after visiting his uncle, and died in a few days.

In another case which subsequently came under Dr. Wells's observation, the patient had been for some time at the bed-side of a female friend who had erysipelas of the face,

‡ Ibid. vol. iii.

§ London Medical and Physical Journal, March 1827.

|| Medico-Chirurgical Transactions of London, vol. xiv.

which proved fatal. Two sisters of this lady, two servants of the family, one of whom had acted in the capacity of nurse, had all the same disorder. Dr. Wells states, in explanation of these facts being regarded as indicating only the great prevalence of erysipelas from some general cause, that he saw no more than two other instances of the disease during the time they happened.

A person, with erysipelas of the face, was brought to St. Thomas's Hospital, where he died. From inadvertence, another patient having a different disease was put into the same bed, before it was properly aired; soon afterwards this patient had erysipelas of the face. Several other persons about this time were attacked with this disease, among whom was an upper nurse, or sister, to whom it proved fatal.

A lady was attacked with fever immediately after delivery, accompanied with erysipematous inflammation of the skin. The infant was seized three days after birth with erysipelas about the pudenda, which spread to other parts of the body, and even to the face. Both the mother and infant died after a few days' illness. The lady's mother and servant-maid, both of whom had nursed the infant, were seized with erysipelas of the face, from which both recovered.

Dr. Stevenson details briefly the results of twenty-one cases of erysipelas, which occurred in his practice in 1821-2. It spread, in many instances, through the members of the same family; in some it appeared soon after visiting friends or relatives during the period of the disease. A person, who was attacked while in attendance on an erysipematous patient, went home to her parents, who resided at some distance, as soon as she was taken ill: they were soon successively seized, and the mother died in a few days.

In corroboration of these facts, Dr. Gibson brings forward other instances which came under his observation in 1822.

A young man, with erysipelas of the face, was brought to his father's house, at the distance of some miles. He ultimately recovered. His master had died a few days before of a febrile disease. The father of this young man was attacked with erysipelas in both hands and arms, which spread to the face. He died in a few days.

The infant son of a gentleman was seized with erysipelas on one foot. The mother was afterwards seized with erysipelas of the face and scalp. The nurse, who suckled the child, was seized with symptoms of pneumonia, and was removed to her father's house four miles off. Her father, who had some days before her arrival received a wound of the scalp, was seized with erysipelas of the face and scalp, and died soon afterwards. A sister, living in the same cottage, had fever with sore throat, from which she slowly recovered. Two children in the same house were cut off with what appeared to be croup. The disease in the sister and children was no doubt erysipematous inflammation of the fauces and trachea.

The next case resembles that related in the paper of Dr. Wells. A woman was admitted into the infirmary of Montrose, with suppuration of the hand, which had followed an attack of erysipelas. Some days after her admission, the patients in the two beds next to her were seized with erysipelas. It was afterwards found that, notwithstanding all the patients were removed from that ward, and the process of cleansing, white-washing, and fumigation adopted, the disease again re-appeared when fresh patients were placed in this ward, so that it became at length necessary to shut up the infirmary for a time.

Mr. Lawrence mentions an instance in which erysipelas of the face, caused by a seton in the neck, seems to have affected two individuals by contagion, producing erysipelas of the face in one, and of the lower extremities in the other.

Diagnosis.—There are few external diseases which, from their resemblance to erysipelas, are likely to render the diagnosis perplexing. The diffused rosy tint of the skin, the uniform swelling, the peculiar burning pains, the tendency of the disease to spread, the vesication or desquamation of the cuticle, and the undefined suppuration and sloughing of the cellular tissue in the advanced stages, are sufficient to point out its nature, and to distinguish it from phlegmon.

Prognosis.—Many general as well as particular considerations influence the prognosis. Some varieties of the disease are more dangerous than others. Simple erysipelas is always a mild disorder; the phlegmonous and oedematous forms are generally severe, often fatal. When the inflammation is extensive, and terminates in gangrene and sloughing of the skin and cellular membrane, the powers of the patient often give way under the disease. It is more dangerous in some situations of the body than in others; for instance, when it attacks the face and head, there is great danger; when it occurs on the chest or abdomen, it is more hazardous than on the extremities.

As a general rule it is more dangerous in elderly than in young persons. Infantile erysipelas is an exception to this remark; this form being extremely fatal, more especially that which commences about the genital organs, and spreads upwards over the abdomen and down the thighs.

Any disease with which the erysipematous inflammation is complicated, has an important influence on the prognosis. When it occurs in persons who have organic disease; when it attacks convalescents from long continued acute affections, or those whose strength is exhausted by chronic disease; when it occurs on the extremities of dropsical subjects, or after severe injuries or surgical operations, the result is doubtful, and therefore the prognosis should be guarded. If again, during the progress of the erysipelas, the brain or any other important organ become inflamed, more especially if the inflammation suddenly leave the skin, and is followed by symptoms of in-

ternal inflammation, there is considerable danger, unless the most vigilant treatment be adopted. Hence in erysipelas of the head, the state of the brain should be minutely watched. When it appears on the chest, the pulmonary organs sometimes become inflamed; or when it spreads to the abdomen, inflammation of the peritoneum or mucous membrane of the intestines sometimes takes place.

Lastly, when erysipelas prevails epidemically, the disease is usually more severe and fatal than when it is sporadic. It is also more fatal at certain periods than at others, from causes which are unknown.

Treatment.—From the account which has been given of the different forms of erysipelas, and from the various conditions of the system under which it takes place, it is evident that the principles of treatment require to be modified according to the symptoms and the circumstances of each case; hence it will be proper to consider the age of the patient, the state of the general powers, the type of the accompanying fever, the seat and intensity of the erysipelatous inflammation, and particularly the duration of the disease.

It is known from experience, that acute disorders do not always bear the same treatment; and this remark applies equally to erysipelatous inflammation. Hence, at one time, strict antiphlogistic treatment may be necessary, while at another period, the system will not bear the same bold measures, although a modification of the same curative principles be indicated. Consequently, in one case it may be necessary to bleed generally and locally,—often to a considerable extent; a second may require topical bloodletting only; in a third, the symptoms often yield to mild purging, saline medicines, and abstinence; in a fourth, from the depression of the system, it may be necessary to administer nourishment and even stimulants, while at the same time blood is taken from the inflamed surface; in a fifth case, powerful cordials are required to support the sinking powers. It may, however, be affirmed that, in the majority of instances, the disease requires antiphlogistic treatment.*

We shall notice the measures to be adopted in the different varieties of erysipelas.

1. Simple erysipelas, being only a very slight form of cutaneous inflammation, in general yields readily to aperients and cooling remedies. If the erysipelas appear on the extremities, it will be necessary not only to abstain from using the limb, but to keep it in the horizontal posture, and to avoid any causes of local irritation, more especially friction. In some cases it may be necessary to apply leeches, and afterwards warm fomentations, or a tepid lotion. Puncturing the inflamed skin with the point of a lancet is a very good mode of local bleeding in slight cases, and may be resorted to in preference to the application of leeches.

* Oportet, si vires patiuntur, sanguinem mittere; deinde imponere simul repimentia et refrigerantia. — *Celsus de Medicina*, lib. v. cap. 25.

2. Phlegmonous erysipelas is, of all the forms of the disease, the most acute, both as regards the local symptoms and the inflammatory type of the fever with which it is accompanied.

The whole aspect of the disease is such as at once to indicate the necessity for active measures.

In general, bloodletting is indispensable; and when the disease occurs in the face and scalp, it is necessary to bleed largely and repeatedly till the head-ach and other symptoms denoting cerebral affection are removed. Local depletion by cupping or leeches, and the application of a cold lotion to the scalp, will form a good auxiliary to the use of the lancet, and in some instances may entirely supersede general bloodletting; indeed, Mr. Lawrence seems disposed to consider the local abstraction of blood more serviceable than venesection.

Active purgatives, antimonial preparations, cooling drinks, abstinence from animal food of every kind, as well as from wine and fermented liquors, and quietude of body and mind, constitute the general summary of the means to be pursued in the commencement of this form of erysipelas. This active treatment is required only when the patient is young and plethoric, and when the local and general excitement is such as to warrant its adoption.

Phlegmonous erysipelas occurs not unfrequently in persons advanced in life, or in individuals whose powers are feeble; in such cases, and in the later stages of the disease, the active measures just recommended would not only be injudicious but positively injurious. In the instances alluded to, the local symptoms may exhibit more or less activity, but still the general powers are weak; topical bleeding therefore, if the powers permit, while we endeavour to sustain the system by nourishment and small quantities of cordials, regulating at the same time the bowels and the various functions according to particular indications, will give the patient the best chance of recovery. Cold applications, composed of equal parts of diluted alcohol, solution of acetate of ammonia and of water, or a lotion consisting of one drachm of carbonate of ammonia, and one of superacetate of lead dissolved in a pint of rose-water, seem to have considerable influence in arresting the processes of effusion and suppuration.

If the erysipelatous inflammation do not yield to the active measures recommended, or if the practitioner be not consulted till the advanced stage of the disease, further depletion will not arrest its progress, but only exhaust the powers of the patient.

The constitutional excitement which characterized the early stage of the disease is succeeded by marks of impaired energy, while the inflammation of the skin and cellular tissue is followed by suppuration and sloughing; and these destructive processes not unfrequently extend over the greater portion of a limb, purulent matter being infiltrated through

the subcutaneous cellular tissue. There is no outlet for the matter unless by sloughing of the skin. Under these circumstances, the practice of making incisions into the diseased parts has been recommended. This plan was suggested many years ago by various writers on surgery, but first practised in this country by Mr. Copland Hutchison. In his *Practical Observations on Surgery*, he recommends these incisions to be made about an inch and a half in length, from two to four inches apart, and varied in number from four to eighteen, according to the extent of surface the disease is found to occupy.

From these incisions fifteen to twenty ounces of blood will generally flow, relieving the tension of the skin, and at the same time giving exit to the pus.

Mr. Lawrence* recommends, in preference to these numerous incisions, one or two long incisions carried through the middle of the inflamed part, in a direction parallel to the long axis of the limb. "These incisions," he says, "are followed very quickly, and sometimes almost instantaneously, by relief and cessation of the pain and tension; and the alleviation of the local suffering is accompanied by a corresponding interruption of the inflammation, whether it be in the stage of effusion, or in the more advanced period of suppuration and sloughing."

"The treatment by incisions," he adds, "is suited to various stages of the complaint; but it is employed to the greatest advantage at the beginning, since it prevents the further extension of inflammation, and the occurrence of suppuration and sloughing. At a more advanced period, the incisions limit the extent of suppuration and gangrene, and at a still later time they afford the readiest outlet for matter and sloughs, and facilitate the commencement and progress of granulation and cicatrization."

Mr. Lawrence does not advise incisions in erysipelas generally, but confines their employment to cases of the phlegmonous kind. This treatment, therefore, is more applicable to erysipelas of the limbs than to the disease when it occurs either on the face and scalp, or on the trunk.

After the incisions, warm fomentations should be applied till the bleeding has ceased; the part should then be enveloped in a warm bread poultice. If the surface of the wound do not discharge freely, it should be dressed, under the poultice, with lint thickly spread with resinous or some other stimulating ointment. When suppuration is established, the matter finds a free discharge at the incision, large portions of cellular membrane are thrown off; and when this process is finished, pressure by a bandage is very useful in promoting the healing process.

Though the bleeding, which takes place from the incisions, is generally serviceable in arresting the inflammatory process, it should

not be checked so long as the pulse is unaffected. The following passage from Mr. Lawrence's paper contains a valuable practical caution. "The great extent to which the hemorrhage may proceed, renders it necessary that we should act very cautiously, especially in elderly persons, or in those whose strength is already impaired by the disease or previous treatment. The patient should be closely watched in such cases until the bleeding has ceased. Should it become necessary to stop the further loss of blood, this may be readily accomplished by tying any bleeding vessels, or placing the limb in an elevated position, or by pressure."

It will be necessary in most instances to allow nutritious diet, and sometimes a little wine to support the powers under the process of suppuration and granulation. We have occasionally found it necessary to give wine and even brandy immediately after the incisions, when the patient has been exhausted by the hemorrhage; but stimulants should be withdrawn after the powers have been restored.

Further experience has confirmed the efficacy of this mode of treatment in cases of phlegmonous erysipelas, and were testimony in support of the practice required, several instances which have been treated by incisions under the directions of the writer of this article might be adduced.

In some cases of erysipelas the accompanying fever is attended with symptoms of gastric irritation; the patient feels hot and flushed; the tongue is red at the point and margin, the body of it being coated with yellow moist fur; there is a bitter taste in the mouth, often accompanied with vomiting of bilious fluid, or diarrhoea.

If the pulse be full, and the general aspect of the symptoms denote acute fever, venesection and leeches to the epigastrium will, in general, quiet the gastric irritation, and relieve at the same time the local inflammation.

3. In the cedematous form of erysipelas the local disease is certainly inflammatory; but the constitutional excitement is seldom such as to warrant those depleting measures which are necessary in the more acute forms. Mild aperients, confinement to the horizontal posture, warm fomentations to the affected parts, and a restricted regimen, comprise all that is in general necessary in the treatment of cedematous erysipelas in its early stage. If the skin of the affected parts feel hot and painful, the application of leeches will be serviceable. Towards the decline of the disease, tonics, especially the sulphate of quinine, with a mild nutritious diet, will be useful.

When erysipelas terminates in gangrene, bark, wine, and opium, with the occasional exhibition of mild aperients, are to be exhibited according to circumstances.

4. In infantile erysipelas, the child's strength should be supported by means of a good nurse. If the milk of the mother be not sufficient,

* Med. Chir. Trans. vol. xiv.

a wet nurse must be procured, and cordials, such as white wine whey, small doses of quinine, and sometimes of ammonia, administered.

5. The tendency of erysipelas to become erratic, or to migrate from one part of the surface to another, has been pointed out. We have also alluded to cases in which the inflammation, after suddenly leaving the skin, has been followed by inflammation of some internal part. When this happens, the organ which has become diseased is to be treated on the same principles as when this inflammation occurs from other causes, while sinapisms are applied to those parts of the skin from which the erysipelas has receded. It is therefore necessary, in all cases of erratic erysipelas, to watch the condition of the internal organs, and to treat with promptitude and decision the symptoms of internal inflammation on their first approach, always however keeping in view the general powers of the patient.

6. When erysipelas supervenes on convalescence from other diseases, the treatment must be regulated according to the circumstances of the case. When it attacks convalescents from fever, it always retards, if it do not render the recovery doubtful. We have seen great benefit in such cases from abstracting blood on the very first appearance of the redness, by making numerous punctures with the lancet, and promoting the bleeding by warm fomentations. In several instances, this practice has at once put a stop to the disease. When it has proceeded after this local bleeding, a cooling plan of treatment with moderate support in cases of great debility, should be prescribed. In elderly persons stimulants, such as sulphate of quinine, ammonia, with wine and cordials, are often necessary.

Some continental surgeons have recommended the application of vesicants and escharotics as local remedies in erysipelas. Dupuytren employs blisters to the affected portions of skin in the second stage of phlegmonous erysipelas. M. Larrey reports favourably of the efficacy of slight cauterization of the surface in traumatic erysipelas.

Mr. Higginbottom, of Nottingham, more recently, has recommended the application of nitrate of silver, with the view of arresting the spreading of erysipelatous inflammation. He conceives that the influence of this remedy (as an external application) is not confined to the textures constituting the skin, but that it extends to the cellular substance, and even to the parts more deeply seated. This remedy is not to supersede active treatment when necessary. It is to be applied in the following manner. The part is to be first washed with soap and water to remove any oily substance from the skin, and afterwards wiped dry; the inflamed and surrounding skin is to be then moistened, taking care that not only every part of the inflamed skin be touched, but the surrounding healthy skin to the extent of an inch or more beyond it. The nitrate of silver is to be passed over

these surfaces once, twice, thrice, in common cases, and more frequently if rapid vesication be required. After the application, the part is to be exposed to the air to dry, and is to be kept cool. Mr. Higginbottom has given, in his work, several cases illustrative of the efficacy of this plan of treatment.*

Compression by a well applied bandage has been employed in the later stages of erysipelas. From what we have witnessed, we are by no means inclined to advise this mode of treatment. If inflammation of the skin and cellular tissue still remain, pressure must prove most injurious; and if there be infiltration of pus in the cellular tissue, it can be of no avail. We have seen more than one case of erysipelas, in which gangrene was induced within twelve hours after a bandage was applied. The only form in which it can be at all admissible, is in the suppurative stage of phlegmonous erysipelas as already recommended, and in the chronic stage of œdematous erysipelas after the inflammation has disappeared from the skin, when the limb continues enlarged from œdematous effusion into the cellular tissue.

(A. Tweedie.)

ERYTHEMA, (from the Greek *ἐρυθμα*, redness,) is one of those nosological terms which has been made use of in various significations by different writers, and its application is, even at the present moment, in some degree vague and arbitrary.

Hippocrates used it in the general sense of a morbid redness of the skin of any kind, for which, at a later period, Celsus, and after him Galen, substituted the term erysipelas; and hence, perhaps, arose a good part of the confusion which we meet with in the subsequent application of the terms. In the system of Sauvages, erythema is synonymous with idiopathic erysipelas. Cullen says, "when the disease is an affection of the skin alone, and very little of the whole system, or when the affection of the system is only symptomatic of the external inflammation," it is erythema; "but when the external inflammation is an exanthema and symptomatic of an affection of the whole system," he calls it erysipelas; and with this Mason Good nearly coincides, applying the former appellation to a local cutaneous inflammation tending to vesication, and the latter to an idiopathic fever producing an erythematic efflorescence. Callisen implies by erythema the lowest degree of erysipelas; and with Rostan, in like manner, it means this same disease in its simplest form. J. P. Frank, however, employs it in a very different signification, confining its use to a morbid redness of the skin of a chronic nature; but in this he is peculiar; at least it is not the sense in which it has been employed by the majority of his countrymen. In Germany, indeed, it

* An Essay on the Use of Nitrate of Silver in the Cure of Inflammation, Wounds, and Ulcers, by John Higginbottom.

seems for the most part to have been confounded, along with some other cutaneous affections, under the common head of erysipelas,* till Rust† restrained the use of the term erysipelas to that species of cutaneous efflorescence which is accompanied with fever, and dependent on disorders of the digestive organs, and drew a line of distinction between this and a similar-looking inflammation of the skin, originating in some local irritation (as excess of cold or heat, chemical agents, or slight wounds,) or in a morbid state of some of the subjacent structures, (as inflammation of membranous expansions, metastatic depositions into the cellular membrane, periosteum, or glands, &c.) This latter affection, whether idiopathic or symptomatic, Rust has distinguished by the appellation pseudo-erysipelas, and it evidently coincides very nearly with the "erythematic inflammation" of many medical and surgical writers in our own country.

In Willan's arrangement erythema signifies "a nearly continuous redness of some portion of the skin attended with disorder of the constitution, but not contagious;" to which Bateman adds, "it differs from erysipelas inasmuch as it is a mere rash or efflorescence, and is not accompanied by any swelling, vesication, or regular fever."

Rayer defines it to be a superficial inflammation of the skin, characterised by morbid redness and heat, and the absence for the most part of papulæ, vesicles, and pustules; and in his latest work he says it is the first stage of a number of cutaneous affections, but when permanent it constitutes in itself a distinct disease; and Billard adds, that as it often ushers in other cutaneous diseases, so it occasionally also forms their termination. Rayer thinks Bateman has fallen into an error in attributing such formidable symptoms as he does to some of his varieties of erythema, as they ought to be referred, not to this trivial inflammation, which is in itself productive of no danger, but to the coexistence of internal affections, chiefly inflammations of the mucous membrane of the stomach and intestines. These, which not unfrequently complicate it, have, he asserts, been overlooked by our English pathologist. The accusation, however, does not appear to us altogether well founded, as Bateman sets out by saying that erythema, like roseola, is commonly only a secondary affection—a mere symptom, though often the most prominent one, of dyspepsia, disorder of the bowels, and other internal derangements.

Having thus past in review most of the significations which have at various times been attached to the term erythema, we have only to add, that the sense into which it has gradually been subsiding in these countries, and in which we mean to employ it here, is that of a superficial inflammation of the skin, which is red and occasionally hot and itchy, but without vesication or obvious swelling. We shall adopt

the primary subdivisions of this affection which have been employed by Rayer, viz. into idiopathic and symptomatic, as at once more comprehensive and more practical than those of Willan and Bateman, all of whose six varieties are easily reducible to the second of the above heads. In reference to treatment, the division into acute and chronic is also most important, and should never be lost sight of in the management of an individual case.

Idiopathic or local erythema is often traceable to some obvious cause of topical irritation, as friction or pressure, extremes of heat or cold, the stings of insects, chemical irritants, distention of the integuments, or, finally, to the inflammation excited on the surface of the neighbouring skin by the existence of some papular, vesicular, or pustular eruption, or by wounds, ulcers, &c.

Of erythema induced by friction (intertrigo), we have a familiar example in that chafing of the skin which occurs especially in fat persons who are inattentive to personal cleanliness. The parts where it usually takes place are about the axillæ, groins, inner and upper part of the thighs, and in the cleft of the nates. It depends on the attrition of the contiguous surfaces in these situations, where the skin is of a delicate texture, and where there is considerable moisture or sebaceous secretion, and much movement of the parts. It very often makes its appearance behind the ears of infants, as well as in the folds of the neck, about the pudenda, back of the knees, &c. The irritated parts secrete in abundance a pale viscid fluid, even before they are excoriated or ulcerated, which concretes into scabs, and seems to be a modification of the secretion of the sebaceous follicles which are very much developed in infants at birth. The itching and irritation of intertrigo in young children is occasionally so considerable as to interfere materially with their rest.

Where the redness is intense, and confined to the circumference of the anus, and a considerable diarrhœa coexists, we may generally consider it as the result of this affection, and produced either by an extension of the inflammation of the mucous membrane of the rectum to the adjacent skin, or by the repeated application of discharges of an unnatural and stimulating quality. A similar irritation and redness occasionally occurs in a chronic form about the verge of the rectum in adults. It is accompanied with distressing itching, and seems for the most part to be connected with deranged action of the stomach and bowels. As it is often accompanied by a copious secretion, which concretes into scales, it is probably more closely allied to eczema than to the subject of the present article, though in many cases it is very doubtful to which it should be referred. (See ECZEMA.) When the redness about the anus and genitals of infants is of a somewhat coppery or livid hue, and resists frequent ablutions and the other simple means usually employed by nurses, we must investigate the case accurately, and ascertain whether the pa-

* Rose, Rothlauf, &c.

† Magazin für d. ges. heilkunde. b. viii.

rents or nurse labour under the suspicion of syphilis in any of its forms.

Erythema often makes its appearance on the cheeks of infants during the period of dentition, and in the neighbourhood of the umbilicus while the chord is sloughing off.

Of the erythematous redness induced by pressure we have familiar examples in the effects of a tight shoe,—of a long ride on one unaccustomed to it,—of protracted confinement to bed and constant lying on the same points of the body. (E. Paratrima of Sauvages.)

Of that caused by extremes of temperature we have instances in the redness of chilblains, and of slight burns and scalds.

The chemical irritants capable of inducing it are numberless. Ammoniacal and other stimulating liniments, blisters, pitch-plasters, sinapisms, turpentine, washes containing lead, and even the long-continued application of linseed poultices, occasionally produce this eruption in very irritable skins. In many instances, however, the presence of vesicles may be detected, and such cases will fall under the head of eczema. The long-continued or repeated application of the urine which occurs in certain diseases of the bladder and urethra; of the fæces in dysentery; or of both, in young infants who are not kept with a sufficient attention to cleanliness; as also the contact of gonorrhœal, leucorrhœal, and other morbid discharges, are frequent causes of this affection of the skin: even the long retention of the natural secretion of the sebaceous follicles around the corona glandis, by becoming rancid and acquiring irritating qualities, may give rise to this inflammation in the prepuce.

We have examples of the influence of distention of the skin in producing erythema, in the redness which sometimes manifests itself over the surface of the most prominent part of tumours, aneurismal and others, of rapid growth; and to this distention may, perhaps, be referred in part the blush of redness which indicates to the surgeon the existence of deep-seated matter, the inflammation of tendinous fasciæ, periosteum, &c.; though, doubtless, much of this depends on sympathy of the vessels of the skin with those of the subjacent parts. The red lines which occur over the track of inflamed absorbents and veins are of a similar nature, as well as the diffused blush over a joint suffering from acute rheumatism or gout. To distention, too, we must attribute the superficial inflammation which so often attacks dropsical parts, especially the lower extremities and scrotum, the skin being put greatly on the stretch by the serous effusion into the cellular membrane. As the anasarca declines, this usually terminates in extensive desquamation of the cuticle; but in less favourable cases, especially in elderly and intemperate people, whose constitutions are exhausted by violent or long-continued diseases of the chest or abdomen, the efflorescence often assumes a dark red or livid hue, and gangrenous ulcers ensue; a termination which is sometimes accelerated by the injudicious use

of scarification, or by an improper mode of performing this operation. In those cases where it is desirable to drain off the water in anasarca, punctures with a lancet are, as Mr. Pott long since pointed out, much preferable to incisions, as they are equally effectual in giving passage to the fluid, and are much less likely to inflame or become gangrenous,—a result which there is so much reason to dread in dropsical habits. Pott gives three cases in which the whole integuments of the penis and scrotum, which were greatly distended by serous infiltration, sloughed off, in consequence of incisions instead of punctures having been made into the swollen parts. M. Fouquier finds that gangrenous inflammation is least apt to ensue when the punctures have been made deep, by plunging the lancet quite through the skin and freely into the cellular membrane. The greater safety of this proceeding may, perhaps, be ascribed to its being more effectual in draining off the water, and thus more rapidly relaxing the integuments, and relieving that state of tension which predisposes to inflammatory action. It has lately been recommended by Dr. Marsh to perforate the anasarcaous swelling in several points with a cataract needle, after which the serum will continue for many days to exude abundantly, and from the smallness of the wound inflicted the risk of inflammation will be much diminished.

Of the erythematous redness induced by the irritation of vesicular, papular, and pustular eruptions, we see frequent examples. Thus the areola of the vaccine vesicle sometimes extends to a considerable distance, so as to cover the greater part of the arm, and in some rare cases even the breast, back, neck, and face. When so extensive, it has usually been described as a species of erysipelas, and is accompanied with a considerable degree of stiffness and difficulty in the motion of the parts affected, with some feverishness and occasional enlargement of the axillary glands. It has been known to turn livid, and has then been sometimes attended with fatal debility. Bateman, we are aware, has classed this affection under roseola. We are not desirous of displacing it, but rest content with pointing out its affinity to the genus under consideration, to which by its origin, apparently from the local irritation of the skin, and by its spreading in a continuous manner, it seems to be very closely allied. Indeed, no very accurate line of distinction is drawn by Bateman between roseola and erythema; and Plumbe has treated of them both together as mere symptoms of internal or constitutional disorder. According to Rayer the inflammation of erythema is of a deeper red and more pronounced character than that of roseola, and sometimes extends to the cellular membrane, or becomes chronic, neither of which is ever the case in the latter. The spots are moreover generally larger, but less numerous than in roseola, in which last they often occur simultaneously in almost every part of the body. After all, we think that these affections graduate insensibly into one another, and

that innumerable cases present themselves in practice which are equally referable to either.

The extensive redness which accompanies some species of strophulus and lichen exemplifies the connection of erythema with a papular disease.

One species of acne (*gutta rosea*) is usually complicated with a diffuse redness, which is of so striking a character as to have led Frank, though incorrectly, to class this pustulo-tubercular affection under the head of erythema. The affected parts of the face, in addition to the characteristic suppurating tubercles, present a shining redness, and occasionally an irregular granulated surface, generally commencing at the point of the nose and spreading gradually to the neighbouring part of the cheeks, and frequently attacking also the forehead and chin. After some years the skin assumes a rough and thickened appearance, and is traversed by a net-work of enlarged veins. It seems often to depend on derangement of the digestive organs, and a peculiar irritability of the stomach in particular; but these are rarely so well marked or so clearly characterised as to enable us accurately to discriminate, or to justify us in attempting to separate, in our classification, the symptomatic from the strictly local examples of this affection. The vividness of the colour of the eruption is greatly increased immediately after making use of any warm or stimulant food or drink, sitting opposite a hot fire, long-continued exposure of the face to the sun's rays, violent exercise, much stooping, reading or writing soon after meals, straining the eyes on minute objects, derangement of the stomach, constipation, or in fine, any of those causes which produce a temporary determination of blood to the head. In young persons who inherit this complaint, it appears in the form of red patches of an irregular shape on the face, from which scurfy exfoliations of cuticle take place from time to time, but the tubercles do not usually appear till a later period. Unless, however, there is a very decided hereditary predisposition to it, or habitual intemperance, it does not usually shew itself till middle life. As the person advances in age, the nose becomes swollen and of a fiery red, the nostrils dilated, and the skin assumes a lobular or tuberculated aspect, with considerable development of the sebaceous follicles which abound in this part. In a case in St. Bartholomew's Hospital in which the nose had from this cause a very unreasonable and inconvenient magnitude, we witnessed the removal of a portion of it by the knife, with considerable improvement to the physiognomy.

According to Frank's definition of erythema, which seems to be entirely drawn from the affection which we have just described, it is a superficial, habitually recurring, or permanent chronic redness of the skin, which grows pale on pressure, and is attended with a sense of itching, heat, and tension, with little real tumefaction or tendency to suppuration. He adds that it may be either smooth or studded with tubercles, and is very frequently accom-

panied with a furfuraceous exfoliation of the cuticle, and he points out the legs and face as its most frequent situation. As long as it is not repelled from the surface, he considers it usually unimportant. The skin becomes thickened, hardened, and deformed by its frequent recurrence. With many it continues throughout life, and with others returns almost periodically, without any evident lesion of other functions of the body. On desquamating, it leaves the skin in a state of increased sensibility, and prone to subsequent attacks. Its causes, he conceives, differ little from those of erysipelas, save in degree and permanence. The passionate, intemperate, and feeble are most liable to it, and suppression of the menses, of hemorrhoids, or of an habitual perspiration in the feet or axillæ occasionally give rise to it.

In the case of irritable wounds, leech-bites, ulcers, issues, setons, and blisters long kept open, the inflammation frequently extends from them to the surrounding skin, and manifests itself by a blush of redness which disappears on pressure. This, when accompanied neither by obvious tumefaction nor tendency to vesication, we should class under the head of erythematous inflammation, rather than under the formidable name of erysipelas, which is frequently bestowed upon it. In a practical point of view, it is desirable that an affection of so slight a nature and requiring so little treatment should have a distinct and appropriate appellation.

Into that species of erythematous efflorescence accompanied with a boggy intumescence of the subjacent cellular membrane, which occasionally supervenes upon wounds received in dissection, we do not mean to enter here, as the dangerous affection of which it is but one out of many more formidable symptoms, will be treated of in another place.

The disease which has been described by some writers under the name of *erythema mercuriale* is a vesicular disease, and will therefore be found under the head of ECZEMA.

The treatment of idiopathic erythema is generally simple. That arising from the chafing of contiguous surfaces may be prevented, for the most part, by assiduous attention to cleanliness, frequent washing with cold water, and the occasional use of the tepid bath. If excoriation has been already induced, emollient applications, as decoction of bran or of marsh-mallows, or a simple ointment, will generally suffice for its cure. In some individuals, however, ointments and greasy applications generally prove irritating, causing an increase of inflammation, and promoting suppurative of the denuded surface. When the part is very painful and considerably inflamed, a solution of the nitrate of silver affords one of the most healing, and after the momentary suffering immediately ensuing upon its use is over, one of the most soothing applications. Fat persons who have been in a state of torture after a long walk, or a hard day's shooting, have often found instant relief from this remedy,

Keeping the part constantly wet with Goulard's lotion is also very effectual.

The intertrigo occurring behind the ears in infants generally requires little more than scrupulous attention to cleanliness, and the interposition of a singed rag to absorb moisture. Such sores as form in this situation, if kept constantly moistened with a weak solution of the acetate of lead, will usually heal rapidly. Most authors, however, caution us against drying them up, dreading from such imprudence the occurrence of ophthalmia, inflammations of the brain, stomach, or intestines, or some other serious complaint; but by taking care to induce a somewhat freer state of the bowels whilst healing these sores, and by slightly reducing the quantity of the child's food, we shall probably in most instances obviate all dangers from this source. In all cases, however, we should endeavour, by attention to cleanliness, to prevent the affection ever going so far that either its existence should be productive of much inconvenience, or its removal of much risk. The advocates of the prophylactic virtues of such sores should be made aware that they often become in themselves, from their painfulness and fetor, and the swelling of the cervical glands which they induce, very troublesome ailments; and that they have even, in some cases, been known to prove fatal by the extension of the inflammation to the internal ear, and to the brain. The sores, too, occasionally become livid and gangrenous, and the child sinks even before the sloughs have separated—a termination which has been mentioned by Burns, who in such cases dwells on the necessity of directing all our efforts to supporting the strength, regulating the bowels, and counteracting the tendency to mortification by the application of camphorated spirits, the fermenting poultice, &c.

Where intertrigo makes its appearance in the folds of the neck, about the arm-pits, groins, or hams, daily bathing, and the occasional exposure of the parts to the air, together with sprinkling them with some unirritating absorbent powder, as tutty, levigated chalk or starch, is all that is usually necessary. Chausier and Plenck caution us against the use of ceruse (carbonate of lead), as being sometimes productive of pains in the abdomen, paralysis of the hands, and all the other symptoms of lead cholic. Yet it is still not unfrequently employed in this country, and we are surprised to find it recommended by J. P. Frank, Mason Good, and Burns, as one of the best preparations for dusting excoriations in children. A lotion containing the sulphate of zinc, and a weak spirituous wash, are often useful applications.

The erythematous inflammation induced by pressure will generally cease on the removal of the cause. Where it occurs from lying long on the same parts, as often takes place in tedious fevers, in phthisis, and in those who are bedridden from other chronic disease, a change of posture, if possible, or the judicious application of pillows, so as to take the

weight of the body off the prominent and inflamed points, are obvious modes of relief. Protecting the skin by chamois leather, soap-plaster, gold-beater's leaf, or white of egg coagulated by alcohol, are expedients to which we are obliged to have recourse when the posture cannot be changed. In low fevers the cutaneous vessels partake of the general debility of the system, and like other weak and irritable parts are readily excited to inflammatory action by the stimulus of pressure. Camphorated and spirituous washes seem, when early applied, to have considerable effect in hardening the skin, supporting the tone of its vessels, and enabling them to resist the influence of the above cause.

The treatment of the erythematous inflammation induced by extremes of temperature is to be found in all systematic surgical works.

The redness ensuing upon the sting of an insect is generally so transitory and trifling as not to require any medical aid. After the extraction of the sting, the application of olive oil with opium and ammonia are amongst the most effectual means of giving relief. The efficacy of ammonia is, probably, in some degree attributable to its chemical action, as the irritating fluid introduced by the sting is generally, as Tiedemann has observed, of an acid quality. A great share of its influence is also, no doubt, ascribable to its changing the mode of the sensibility in the irritated parts.

That species of erythematous efflorescence which is brought on by the application of chemical agents to the skin, usually ceases speedily after their application has been omitted; and its disappearance may be accelerated by emollients, fomentations, and other measures, which at once tend to remove all remains of the irritating substance, and to relax and soothe the excited skin. Where the irritating matter is of a resinous nature, oily applications will greatly facilitate its removal.

When the contact of urine and faeces is the source of the evil, frequent changes of linen are indispensable, and every effort should be made to keep the parts clean and dry. The detail of the expedients which have been devised for the fulfilment of this object is to be found in such works as treat of diseases and injuries of the bladder, urethra, &c.

When erythema results from the distention of the skin by tumours of rapid growth, relaxant applications under some circumstances, and the application of leeches and cold under others, are called for; but as such cases usually fall under the care of the surgeon, we shall not dwell on them here. Where this inflammation is induced by anasarca distention, a horizontal posture is very important, and frequent fomentations, and keeping the limbs enveloped night and day in lint moistened with water, and the whole wrapped up in oiled silk, so as to prevent too rapid evaporation, are measures which tend notably to diminish tension by keeping the skin in a relaxed and perspirable state, and which have likewise great influence in subduing local inflammation. When the

inflamed surface assumes somewhat of a livid or brownish hue, and threatens gangrene, the use of dilute spirituous and camphorated fomentations is the common practice, though the propriety of it is not universally acknowledged. Those who look upon inflammation as the source of all the danger, prefer soothing applications throughout. Whilst using these local measures, we must at the same time endeavour to promote the absorption of the effused fluid, support the strength, and combat disease of the heart, lungs, serous or mucous membranes, which so often co-exists in these cases, and as being the principal cause of all the other symptoms, demands our chief attention.

When the irritation of some papular, vesicular, or pustular disease seems to be the exciting cause of erythema, the latter may generally be disregarded, provided we take the proper steps for relieving the primary affection, and these will probably for the most part be found in the due employment of soothing or antiphlogistic measures. In that species which so often complicates acne, where it is constitutional, a cure need hardly ever be expected, as it seems to depend in some degree on a varicose state of the minute veins. Cold evaporating and slightly astringent lotions, with moderate but long continued pressure, are almost the only measures which afford permanent benefit in varicose affections of the smaller veins in other parts of the body; but they are, if not wholly inapplicable in this situation, at least too inconvenient to give them any chance of being steadily and long enough employed. Very great temperance, regular exercise, and avoidance of all those causes which we have pointed out as tending to exasperate this affection, should be strongly enjoined. Where the scurfiness is considerable, some mild ointment is useful in removing or concealing it. If the affection be purely local, slightly astringent lotions of lead or zinc, with a small portion of alcohol or vinegar, may be tried, or ointments of a similar nature; but they will too often prove nugatory in their effects. The popular use of water-cresses and other raw vegetable matter, under the name of antiscorbutics, is highly irrational. A somewhat tonic regimen, and the use of flesh-meat in preference to an exclusively vegetable diet, are proper. We have lately met with a striking exemplification of this in the case of a distinguished artist, in whom this affection, induced by the habitual stooping which the exercise of his profession required, was greatly and suddenly aggravated by a strict adherence to a vegetable diet, and again diminished considerably on his returning to the free use of flesh-meat. The distention and acidity of stomach which an excess of vegetable food often induces, assist us in explaining its injurious effects in such cases. Where the eruption depends upon some chronic derangement of the digestive organs and an irritable state of the stomach, little can be expected from topical applications. Stimulants (and most of the empirical lotions for this

affection contain corrosive sublimate, and are of this nature,) are usually injurious, and to remove this efflorescence by astringents, where possible, might do much mischief, by exasperating the internal disorders from which they spring. Alkalies internally seem sometimes useful, which is attributable, probably, to their antacid power, and their directly soothing effects on the mucous membrane. The regulation of the functions of the stomach, bowels, and liver, with a careful attention to the diet, are the most important points in endeavouring to prevent its increase.

The redness of the skin which is occasionally induced by inflamed ulcers, leech-bites, painful issues, &c., in addition to such internal antiphlogistic means as the existing state of the system may appear to indicate, requires locally merely the application of a bread-and-water poultice, or of lint, moistened with cold water and enveloped, as directed above, in oiled silk, to prevent its drying rapidly by evaporation. The erythematic inflammation succeeding to the use of leeches seems often to be induced, not so much by the irritation of the wounds they inflict, as by that excited in them by the subsequent application of Goulard and other astringent tonics. Where it is necessary to apply cold to a part immediately after leeches have fallen off, by confining ourselves simply to the use of cold water, in preference to these medicated lotions, we shall rarely have the mortification of seeing this cutaneous affection, which is often very annoying to the patient and his attendant, ensue; whilst, at the same time, the temperature may, by means of the coldness of the water and its gradual evaporation, be regulated quite as effectually.

Symptomatic erythema is associated with many inflammatory affections, especially those of the mucous membrane of the stomach and intestines; and the symptoms which have been by some attributed to the cutaneous affection are really, as well as itself, dependent on the state of the internal organs. The measly efflorescence so common in our continued fevers of some years, is a striking example of the sympathy of the cutaneous system with the mucous membrane. In dysentery, too, exanthematous efflorescences occasionally occur, and sometimes, according to Chomel, form a salutary crisis to the disease.

The erythema of Willan and Bateman, of which we have already given the definition, nearly coincides with Rayer's erythema symptomaticum, and has been divided into six varieties. In some of these the eruption is more or less elevated at some period of the course, thus slightly approximating them to the papular and tubercular classes; but these elevations are obscure and soon subside. Willan has, however, availed himself of their temporary existence to form the ground-work of some of his subdivisions.

1. *Erythema fugax* (maculæ volatiles) consists of evanescent red patches of an irregular figure, which appear successively on the breast, neck, arms, and face in various febrile dis-

orders, in bilious diarrhœa, in chronic affections of the primæ viæ, dyspepsia, hysteria, &c. The heat of the affected skin is increased, and the disappearance of the patches is not accompanied with any evident desquamation.

2. *Erythema laxe* of Bateman coincides almost, if not altogether, with the species which we have already described as depending on dropsical distention. He dwells on the usual coexistence of anasarca, on the smooth shining surface, its appearance chiefly on the lower extremities, and its termination in desquamation, and says it may occur either in sedentary young persons, in whom exercise, diuretics, and corroborants will contribute to shorten its duration, or also in elderly or anasarca subjects, especially if intemperate, and is liable to terminate in gangrenous ulcers. The distended skin is often chequered with patches of a dark red or purple hue. Horizontal posture, diuretics and bark, with weak spirituous lotions, are recommended by him. He adds, that it sometimes occurs without œdema where the bowels have been much disordered, and occasionally is worse at the menstrual period.

3. *Erythema marginatum* occurs chiefly in old people on the loins and extremities in the form of patches, which are in some places obscurely papulated, and are bounded on one side by a hard, elevated, tortuous, red border, but are not regularly defined on their open side. They have an uncertain duration, and are not productive of any irritation in the skin. They are connected with some internal disorder, and are usually an unfavourable symptom.

4. *Erythema papulatum* consists of large, vivid, red, irregular patches, chiefly on the arms, neck, and breast, generally preceded for a day or two by obscure papulæ, which give a roughness to the skin. The eruption, after continuing about a fortnight, becomes bluish, especially in the centre of the patches, and gradually declines. There is occasionally, though not always, considerable constitutional disturbance, indicated by a small frequent pulse, anorexia, and great depression, with severe pain and tenderness of the limbs. The treatment consists in light diet, diaphoretics, the mineral acids, and attention to the state of the bowels.

5. *Erythema tuberculatum* occurs, like the preceding, in large irregular red patches, but through these small tumours are dispersed, subsiding in about a week, and leaving the erythema behind them, which, becoming livid, disappears in about a week more. It is usually ushered in by fever, and is accompanied with languor, irritability, and restlessness, and is succeeded by hectic. It is so rare, that Bateman himself never saw it, and Dr. Willan, on whose authority he gives it, met with but three cases, and medicine seemed to have no effect either in alleviating them or in warding off the subsequent hectic.

6. *Erythema nodosum* seems peculiar to females, and occurs chiefly about the shins. It is preceded by slight febrile symptoms,

which cease on its appearance. It presents itself in the form of oval patches, with their long axis parallel to the shin bone. They rise slowly into hard and painful protuberances, which gradually subside within nine or ten days, their colour about the same time turning bluish. It is a mild affection, requiring usually only laxatives, mineral acids, and other tonics. We have known it, however, return frequently in the same individual, attended with considerable œdema, and after terminating in desquamation, succeeded by severe pains in the limbs, which demanded the employment of pediluvia, bandages, &c.

To these six varieties mentioned by Willan and Bateman, we give a seventh, *general erythema*, on the authority of Rayer, who says it has been overlooked by most writers on cutaneous diseases, or confounded by them with erysipelas. It consists in a superficial redness of the skin unequally distributed over various parts of the body, and occasionally differing but slightly from the natural colour of the integuments, and unaccompanied by swelling or vesications. It is attended with heat and dryness of the surface, and its duration rarely exceeds a week. The redness may be continued or intermittent, or appear only momentarily, during the exacerbation of gastro-enteric or other acute internal inflammations. It often disappears on the approach of death. In those who recover, desquamation and falling out of the hair one or two weeks after the disappearance of the eruption, often occur.

This species, and, indeed, all cases where the erythema presents itself in an acute form, require antiphlogistic regimen, and occasionally venesection, with cooling and emollient lotions and the tepid bath.

In the chronic varieties of erythema, Rayer recommends leeches to be applied round the affected parts, together with tepid and vapour baths, or the douche impregnated with sulphuretted hydrogen. Where the cutaneous inflammation depends on some evident derangement in the stomach or intestines, the application of leeches in the neighbourhood of these organs may also be necessary.

(W. B. Joy.)

EXANTHEMATATA.—The word *exanthema*, derived from the Greek term ἐξάνθια, to *effloresce*, or *break forth*, was applied, by the Greek writers, to cutaneous eruptions generally. By modern authors its application is confined to cutaneous eruptions accompanied with fever, arising from specific contagion.

In the nosology of Cullen, the *exanthemata* constitute the third order of the class *Pyrexia*, and we find he has included ten different genera, viz. *variola*, *varicella*, *rubeola*, *scarlatina*, *pestis*, *erysipelas*, *miliaria*, *urticaria*, *pemphigus*, and *aphtha*. It is evident, however, he has included not only the eruptive fevers, strictly so called, but those diseases in which a vesicular efflorescence occasionally appears in their progress. Plenck, Frank, and others have fallen into a similar error. Willan and Bate-

man classify the exanthemata according as the eruption agrees with their definition of an exanthema or rash, viz. "superficial red patches, variously figured and diffused irregularly over the body, leaving interstices of a natural colour, and terminating in desquamation of the cuticle." They therefore comprehend, under exanthemata, *rubeola*, *scarlatina*, *urticaria*, *roseola*, *purpura*, and *erythema*.

In the article FEVER will be found the classification of fevers we propose to adopt in this work, viz. into 1. *continued*; 2. *periodic*; and 3. *eruptive*. The eruptive fevers comprehend those diseases which we submit should alone be included in the exanthemata, viz. *variola* (and its modifications), *rubeola*, and *scarlatina*. In those diseases which bear a strong analogy to continued fever, we find that a certain order of febrile symptoms is followed by a particular eruption; that the fever and exanthema run a definite course; the efflorescence going through a regular series of changes, and terminating in desquamation of the cuticle; that these eruptive fevers occur only once during the life of the individual; and, lastly, that they are communicated by contagion.

The regularity of the eruptive fever and the progress of the efflorescence are most precise. The eruption of *small-pox* appears on the third day from the commencement of the febrile indisposition, and matures on the tenth; the rash of *measles* appears on the fourth, and declines on the seventh day; and the efflorescence of *scarlatina* is visible on the second day, and begins to disappear on the fifth; the progress of the fever being thus fixed and regular, and apparently keeping pace with the series of changes which the eruption successively undergoes.

The circumstance that eruptive fevers occur only once in the course of life, though correct as a general rule, is liable to occasional exceptions. These, however, are comparatively so few, that they tend much to confirm this principle. Persons on the other hand occasionally escape one or other of the eruptive fevers; more frequently, however, *scarlatina* than either *small-pox* or *measles*.

The last characteristic of the exanthemata—that they are communicable by contagion—admits of positive proof as to *small-pox*, in the communication of this disease by inoculation.

Dr. Home* succeeded in communicating measles by introducing the blood of a patient affected with the disease into the system of another individual; and the evidence of the contagious nature of scarlet fever is so strong, that no one in the present day ventures to impugn the doctrine. (See MEASLES, SCARLATINA, SMALL POX, and VARICELLA.)

(A. Tweedie.)

EXPECTORANTS, (from *ex* and *pectus*; *expectoro*, *expectorans*, *Expectorantia*.) are medicines intended to promote the excretion of mucus and other substances from the

trachea, its branches, and the bronchial cells. In offering this definition, it is proper to mention that the existence of any substances capable of unloading the pulmonary tubes has been doubted; but experience has demonstrated that not only substances applied in the form of vapour or of gas to the parts now mentioned, promote expectoration, but that substances taken into the stomach produce the same effect.

The mucous membrane of the air-tubes of the lungs is the part intended to be influenced by expectorants. This membrane, which lines the whole of these tubes, from their origin, through their trunk, the trachea, and 'all its ramifications, to their termination in the bronchial cells, secretes a lubricating bland mucus, in appearance not unlike a thin solution of gum, intended to mitigate the action of the air on a highly irritable surface. When this mucus is accumulated, or becomes viscid and adheres to the sides of the bronchial tubes, or when it is inspissated or rendered acrid by inflammation excited in the membrane, so as to impede in any manner the function of respiration, then expectorants become useful by contributing to its removal. In effecting this, they operate in two distinct ways: 1. they either diminish the action which has produced the preternatural secretion, and thereby enable the natural effort of coughing to remove the morbid matter already existing in the air-tubes, or, 2. they directly operate on the respiratory nerves, and powerfully excite those muscles the sudden simultaneous action of which is necessary for expelling the morbid matter. It is easy to conceive in what manner gaseous substances introduced into the lungs may promote this expectorant effort; but the question naturally suggests itself, do the substances taken into the stomach proceed to the lungs, and there exert their influence?

Many substances, when introduced into the system through the stomach, escape by the lungs. Thus, various odorous matters, oil of turpentine, ether, alcohol, phosphorus, and camphor, soon after they are taken into the stomach, become perceptible in the breath; and this is the case, also, when they are introduced into the system by other channels. M. Breschet and Dr. Edwards having injected oil of turpentine, in small quantity, into the crural vein of a dog, found that it was soon afterwards strongly exhaled from the lungs, although no odour of it was perceived on exposing the peritoneum.* From these and other facts it is evident that the lungs afford exit to substances which have entered the circulation: now, in admitting this, it is not unreasonable to suppose that some of the medicines administered with the intention of promoting expectoration also enter the circulation, and proceeding to the lungs, excite there the expectorant effort. But, although this conclusion be highly probable, yet it must be admitted that it is not susceptible of demonstration.

* During this experiment, if a portion of the surface was denuded and a cupping-glass applied over it, the odour was not then perceptible in the breath.

* Clinical Experiments.

All expectorant substances may be arranged under two heads.—1. those which effect the excretion by *topical* means; 2. those which effect it by *general* means.

1. *Topical expectorants*.—These may operate in two ways: *a.* they may directly stimulate the nerves regulating the action of the respiratory muscles, and, by exciting these to sudden action, may effect the excretion by coughing; or, *b.* they may compress the thoracic viscera by producing vomiting, and thus induce a sudden and forcible expiratory effort so as to effect the expulsion of matters from the lungs.

a. In explaining the manner in which the first kind of topical expectorants operate, it may be useful to consider briefly the nature of coughing. The act of coughing is a short and forcible expiratory effort, frequently repeated, the inspirations, in the intervals, being trifling in comparison with the expirations. Any irritation affecting the glottis, and acting upon a branch of that series of nerves which supply the respiratory muscles, excites involuntary coughing; but the action thus excited may be moderated, if it cannot be wholly checked and terminated, by the will of the individual. Coughing, whether voluntary or involuntary, is the result of the irritation of a certain set of nerves, and is intended to relieve the bronchial system of some offending cause; it is, therefore, a salutary phenomenon. In those debilitated by disease or other causes, the difficulty of exciting the act of coughing with force sufficient to produce the salutary effect, is so obvious as to strike the ordinary as well as the professional observer. The distress arising from this circumstance, the uneasiness caused by the irritating matters which coughing forcibly would readily remove, and the feeling of suffocation experienced from the accumulation of mucus obstructing the free passage of the air to the bronchial cells, are very considerable. In such states of the chest, the topical application of a stimulant to the bronchial nerves may so far rouse the exhausted excitability as to enable the muscles to perform the necessary effort; whilst, at the same time, the substances employed to produce this effect may be of a nature to prove also beneficial, by imparting a renewed healthy action to the diseased mucous membrane. The whole of the substances, arranged under this head, it must be recollected, stimulate so much as to require the utmost caution in their administration; but as the atmospherical air is the vehicle by which they are conveyed into the lungs, there is no difficulty in apportioning the degree of dilution so as to regulate the quantity of stimulus required or admissible.

The substances employed for the purpose of stimulating the mucous membrane of the bronchial system by direct application, and through it stimulating the respiratory organs, are few, and of these a small proportion only are in use.

Benzoic acid may be employed either in its separate pure form or at the instant of its

extrication from benzoïn. In either case it requires to be largely diluted with atmospherical air, and combined with aqueous vapour. If the crystallized acid be employed, half a drachm should be put into an inhaler, and volatilized by the heat of a spirit-lamp; or, if the crude benzoïn be preferred, half an ounce of it should be broken into small morsels and treated in the same manner. In the first instance, the diluted acid is the stimulating agent; in the second, the volatile oil, mixed with a small portion of the acid, rises with the aqueous vapour. Both are said to have proved beneficial in phthisis, even after the existence of suppurating tubercles had been clearly ascertained. The writer of this article has never employed these stimulants in phthisis; but he has seen much advantage derived from them in spasmodic asthma, in shortening the paroxysm and promoting expectoration.

Acetic acid acts nearly in the same manner as the benzoic. It is the oldest of the topical remedies of this order, is more manageable than the acid of benzoïn, and does not require the aid of boiling water for its elevation. It is usually extricated from diluted vinegar; but as this contains sulphurous acid, distilled vinegar should be employed.

Chlorine is of very late introduction as a topical expectorant. It may be breathed by mixing it with the common air of the apartment of the patient, at the moment of its extrication from chloride of lime or of soda; or from a mixture of one part of peroxide of manganese and four parts of muriatic acid.* The former is to be preferred when a moderate stimulus only is required; but in general, for expectorant purposes, chlorine is obtained by expelling it from its saturated solution in water by the aid of gentle heat.

If an attempt be made to breathe chlorine in its undiluted state, it does not enter the lungs, but produces a powerful spasm of the glottis; and, if this be not immediately relaxed, suffocation ensues. When it is diluted with a moderate portion of air, it excites violent coughing, irritation in the bronchial cells, great dyspnoea, and a painful, anxious sensation in the chest, which continues for several days. When largely diluted it operates as a salutary stimulus to the mucous membrane.

In its largely diluted state, chlorine gas was first proposed as a topical expectorant

* In this process the muriatic acid, which is a compound of hydrogen and chlorine, is partially decomposed; and decomposition of the peroxide of manganese also takes place. The liberated hydrogen of the muriatic acid unites with one equivalent of the oxygen of the peroxide of manganese, and forms water; whilst the chlorine is set free in a gaseous state. This gas is of a greenish yellow colour, and has a pungent, acrid, suffocating odour. It is readily absorbed by water; but the solution, unless kept in a blackened bottle or a dark place, is changed in its character by slow decomposition of the water and the formation of chloric and muriatic acids. Its goodness is known by testing it with litmus paper: if good, it will destroy the colour of the paper; if it contain the above-mentioned acids, the paper will be reddened.

by Dr. Favart of Marseilles in 1804. Soon after that period the writer of this article became accidentally acquainted with its value as a topical expectorant, from witnessing its beneficial influence in a severe case of epidemic catarrh, when extricated as a fumigation to check infection; and he has employed it occasionally from that time in pulmonary diseases. But it was scarcely used either in this country or on the continent, until a report of Dr. Cottureau, of the Faculty of Medicine of Paris, again brought it before the profession. Several trading chemists, in particular M. Gannal, had remarked that phthical persons, who engaged themselves to work in the manufactories of bleaching liquor, in which chlorine is largely extricated, were gradually but evidently improved in health: to confirm his observations, M. Gannal constructed an instrument for inhaling it, and actually administered it as a remedy in phthisis. The success of his experiment surprised him; but not being a medical man, he mentioned his views of the subject to Dr. Cottureau, who pursued the same plans as M. Gannal, and with a degree of success sufficient to merit the attention of the profession. The same influence of chlorine in pulmonary diseases has been observed by Mr. Tenant, of Glasgow, who informs us that all the men who engage themselves to work in his manufactory, if they have coughs, are rapidly relieved when gradually introduced into the chlorine house; and of late, people labouring under phthisis and asthma have taken lodgings in the neighbourhood of his works, for the sake of the atmosphere of chlorine emanating from them.

The best method of inhaling chlorine is to put $f\text{3i}$ or $f\text{3ii}$ of the saturated aqueous solution into a glass inhaler, and to add to it $f\text{3ii}$ of hot water, which gradually drives off the chlorine. This quantity may be inhaled every five or six hours, so as to maintain the effect produced on the mucous membrane. When it is thus cautiously inhaled, the evident effects are a slight sensation of constriction in the thorax, with some increase of cough; in a few instances a trifling degree of vertigo has been experienced, but these feelings rapidly subside; expectoration is produced almost without an effort, and the patient gradually becomes more comfortable than before inhaling the gas. In cases of asthma the relief is peculiarly striking; and in phthisis we have observed that the symptoms of hectic have much abated during its employment; but we have seen no instance of the latter disease cured by it.

The beneficial operation of chlorine may depend on its stimulus producing a new action on the diseased surface, which, if it could be maintained for a sufficient length of time, might overcome the morbid action; and by supporting the tone of the system by other means, without exciting fever, the disease might be cured. In cases where large vomicae exist, it is in vain to expect a cure from any means; but if we reflect on the influence of chlorine in improving the discharge from diseased mucous

surfaces, such as that of the nostrils in coryza, and in promoting the cure of external ulceration, it is not a vain speculation to expect much advantage from its inhalation in phthisis.

When chlorine is inhaled without being sufficiently diluted, the irritating effects are only temporary: very few instances have occurred in which inflammation has supervened. Indeed to no other irritant gas does the pulmonary system so rapidly accommodate itself; the workmen in the manufactories of bleaching liquor breathe it daily in large quantities with impunity. The best method of overcoming its deleterious effects is to inhale ammonia largely diluted with aqueous vapour or ether; or, if neither of these be at hand, to inhale simple warm vapour.

The substances which operate topically, either by stimulating the pulmonary exhalents, or as sedatives relieving the constriction on these vessels, and thereby facilitating expectoration, are also few. In those unaccustomed to the use of the former, they undoubtedly excite coughing; but in such cases the spasmodic action is produced by their first impression on the glottis, for when they are admitted into the trachea, no coughing is produced. The first of these, the fumes of boiling tar, was recommended as a remedy in phthisis by Sir Alexander Crichton, who had seen it employed in Russia. It produces in general much increase of cough; but this soon abates, and the expectorated matter is, in most instances, much improved. These effects seemed to promise the most salutary results; but like some other remedies which have been occasionally introduced to the notice of the profession, the vapour of tar suffered from being overpraised, and from too sanguine expectations being formed relative to its powers, and it fell into neglect.

Another vapour which operates nearly in the same manner as that of tar has been much employed in America, the fumes arising from burning undressed wool. The use of these vapours was first recommended by Dr. Physick, who had found them extremely serviceable for stimulating and healing external sores, and concluded that they might prove equally beneficial if inhaled into the lungs. He conceived that he had established the fact of their utility in phthisis; but the experience of a few instances in which they were tried by the writer of this article does not authorize him to pronounce very favourably respecting their employment. They excited great coughing when they were first used; but this rapidly subsided, and some degree of comfort was certainly experienced after each time of inhaling them: but nothing more resulted from their employment.

The sedative topical expectorants are better known. Tobacco, when smoked, has been long employed for allaying the violence of the paroxysm in spasmodic asthma; but it is uncertain whether the benefit should be ascribed to the nicotina or the volatile oil. The use of stramonium, in the form of smoke also, has been found highly useful, and was at one time a favourite remedy in asthma. It appears

to produce its beneficial effect in two ways. In the first place, it is directly applied to the mucous membrane when this is in a state of great irritability, and by acting as a sedative and allaying this condition, it favours the slower and more perfect secretion of the mucus, which being thus brought into a more natural state is consequently more easily excreted: in the second place, by influencing generally the nervous system, the spasmodic symptoms attendant on the paroxysm of asthma are allayed, and respiration proceeds in a calm and undisturbed manner. The powers of stramonium were, at one time, greatly over-rated; but experience has sufficiently demonstrated that it is capable of mitigating the violence of the paroxysms, although it may not be able to establish permanent relief from their attacks. Dr. Bree has objected to the employment of stramonium on the supposition that it induces a tendency to apoplexy; but this is, at best, problematical.

b. The second set of topical expectorants, those which operate by mechanically compressing the thoracic viscera, and thus induce a sudden and forcible expiratory effort, so as to affect the expulsion of matters from the lungs, are emetic substances. In the operation of vomiting, by the sudden and violent contraction of the abdominal muscles, in order to force the contents of the stomach upwards, an impulse is communicated to the whole bronchial system, and by this means the expiratory effort being rendered more forcible, the expulsion of the mucus is effected. The beneficial effect of emetics in clearing away mucus accumulations from the lungs is indeed well known; and frequent recourse is had to them in many of the pulmonary diseases of children with uniform advantage. It might be supposed that the best emetics to select for expectorant purposes, would be those which operate by directly stimulating the nerves of the stomach, and which call the muscles necessary in the mechanism of vomiting into immediate action; but experience has demonstrated that the antimonial preparations are better suited for this purpose than any other emetics. Besides aiding the expulsion of mucus from the bronchial tubes, they possess the power also of controlling inflammatory action. The employment of emetics for procuring expectoration was formerly in much vogue as a remedy in phthisis. The emetics for this purpose, however, were seldom selected upon any principle: at one time we find sulphate of zinc and sulphate of copper employed; at another, antimonials, ipecacuanha, and other nauseating emetics. If the lungs be loaded with mucus, and little or no febrile action be present, the direct emetics are to be preferred; for in this case the mechanical impulse only is required; but if, in promoting expectoration, we are desirous of maintaining nausea afterwards, then the best emetic is the vinous solution of the tartrate of antimony and potassa, given to the extent of $\text{ʒ} \frac{3}{4}$ vi for a dose, in a solution of the extract of liquorice. Squill and sulphuret of potassa have also been employed to excite vomiting to aid their expectorant properties.

2. *General expectorants.*—These operate either by being received into the circulation, or through sympathy with the stomach: the first stimulate the pulmonary exhalents through the medium of the circulation; the second affect the excretories by the nausea which they induce.

a. The first of the *organic* substances which operate by stimulating the pulmonary exhalents is *emetina*, the active principle of ipecacuanha. In its uncombined state it has not been much employed in Britain; but in France it has been successfully administered in doses of one-eighth of a grain, three or four times a day, in whooping-cough; and in doses of a quarter of a grain it proves useful in catarrhal affections. It produces expectoration without exciting nausea; and we can readily comprehend how this is effected, if we admit that it is received into the circulation and determined to the lung as its emunctory: but if this be not admitted, it is difficult to explain its mode of acting:—its beneficial influence is undoubted. When ipecacuanha itself is administered, it is usefully combined with opium, in the form of Dover's powder, of which from three to five grains produce expectorant effects, when neither nausea nor diaphoresis result. The French physicians assert that ipecacuanha is less useful in pulmonary diseases than uncombined emetina, owing to a peculiar fatty matter which it contains interfering with the influence of the emetina. This opinion is merely hypothetical; but nevertheless the evidence which experience has afforded in favour of the expectorant power of emetina is sufficient to recommend it to the favourable notice of British practitioners.

The value of *squill* as an expectorant has been long known: it is supposed to depend on a peculiar principle which has been named *scillitina*. If this opinion be correct, it is probable that the squill undergoes decomposition in the stomach, and that the *scillitina* only is conveyed to the lungs. This opinion, however, is as yet unsupported by proof; and much obscurity still involves the mode in which squill produces its expectorant effect. Squill is contra-indicated in all diseases of an inflammatory type. It is usually administered in combination with honey and vinegar in the form of an oxymel, or in tincture, or as a pill in combination with soap and ammoniacum. In these forms it is prescribed with advantage in asthma and chronic catarrh. The dose should not exceed one grain of the dried bulb, as in larger doses it is apt to prove emetic, purgative, or diuretic: one drachm of the oxymel, seven grains of the pill, and thirty minims of the tincture, are equivalent to this quantity of the dried bulb. When overdosed, squill excites the most violent vomiting, purging, and convulsions, symptoms which induced Orfila to refer its operation to the nervous system; an opinion partly confirmed by the fact that dissections of persons poisoned by squill present no appearances of inflammatory action in the pulmonary system. The best antidotes are ammonia and the alkalies, on

which account these substances are incompatible in prescriptions with squill.

Several of the gum resins are generally regarded as useful expectorants, but the expectorant property of some of them is doubtful. *Myrrh* is one of these, and assuredly we have never seen it produce expectoration when given alone: conjoined with ipecacuanha or squill, it proves useful in the chronic coughs and catarrhal affections of debilitated habits; but in these cases more is due to its tonic than its expectorant influence. It is frequently prescribed with the view of supporting the system in the advanced stages of phthisis; and, probably, no medicine is better adapted for this purpose during a course of the inhalation of chlorine. At best, however, it can only be regarded as an auxiliary. In prescribing myrrh, it should be recollected that its aqueous infusion precipitates salts of lead, which are, consequently, incompatible in mixtures with it. In phthisis it is advantageously combined with sulphate of zinc or salts of iron; and when there is much acidity of stomach, it may be dissolved in liquor potassæ or ammoniæ, and administered in any bland fluid or aqueous solution, such, for instance, as the bitter almond emulsion. Its efficacy as an auxiliary is well established in chronic catarrh and humoral asthma, in both of which diseases its tonic influence is beneficial in relieving the exhaustion which follows the profuse expectoration. The dose of myrrh, in such cases, is from four to ten grains, repeated every third or fourth hour.

As an expectorant, *ammoniacum* has been found useful in asthma, peripneumonia notha, and the chronic catarrh of old age; it has also been prescribed in tubercular phthisis. It is seldom given alone, but usually in combination with squill or antimonials. In America it has lately been conjoined with nitric acid: two drachms of it are triturated with f^{ss} of nitric acid, and then formed into an emulsion with f^{ss} of water. A table-spoonful of this solution in a cupful of any bland fluid is administered every second or third hour, in cases of old catarrhs, when there is an infarction of the lungs with viscid mucus, which the patient has not strength to expectorate. It may, in this state, certainly rouse the energy of the respiratory muscles; but we doubt whether it is equal to ammonia or its carbonate in such cases. It may, however, be administered in conjunction with ammonia; and, when thus combined, no other expectorant produces so much benefit in those irritable coughs which accompany hysterical affections, and are attendant on dyspeptic and hypochondriacal conditions: the expectoration becomes freer and more abundant, the oppression diminishes, and the patient is rendered altogether more comfortable. *Ammoniacum*, Galen informs us, was employed by Crito as an expectorant in phthisis; it formed the chief ingredient of the pilulæ balsamicæ of Morton, which held at one time a high reputation; and many other writers have recom-

mended it in this merciless disease. It may prove useful in promoting expectoration where it is deficient, and may have a tendency to allay irritation; but the experience of modern practitioners has not confirmed the encomiums of their predecessors with respect to its value as a remedy in phthisis. The dose of *ammoniacum*, in these cases, is from eight to ten grains, administered three or four times a day. In large doses it causes nausea, thirst, and a sensation of heat at the stomach. The emulsion is the best form of administering *ammoniacum* as an expectorant; but as the gummy matter is not sufficient to suspend the resin for any length of time, it should be combined with mucilage. The dose of the mixture is from f^{ss} to f^{ss} : it is coagulated by the oxymels, and cannot be combined with spirit of nitrous ether.

Assafetida was regarded by Cullen as superior to *ammoniacum* in spasmodic asthma; and in phthisical cases, when there is much flatulency, Dr. Parr considers it valuable as combining cardiac and expectorant properties. It possesses, however, no advantages over *ammoniacum*, and is more heating: indeed, what has been said of *ammoniacum* applies equally to it, galbanum, and sagapenum; they are all stimulant expectorants, and may be administered, under similar circumstances, in the same doses and in the same manner.

The balsams employed as expectorants are those of *tolu* and *peru*, *styrax* and *benzoin*. All of them were formerly much used in affections of the chest, whether recent or chronic; but there can be only one opinion respecting the impropriety of administering balsams in inflammatory states of the lungs. Independently of the benzoic acid which they all contain, and which is powerfully stimulant, the volatile oil, which is another of their components, contra-indicates their administration in cases of excitement. Dr. Fothergill denounces the employment of balsams in pulmonary diseases at any period of the attacks, but he carried his objections too far; and there is sufficient evidence to prove, that after the excitement is subdued, there are circumstances which not only admit of the administration of balsams, but in which they have been found highly beneficial. They are best administered in the form of emulsion, made by triturating the tincture of the balsam with mucilage of acacia gum, which renders it miscible with water; and in this form they may be usefully combined with ipecacuanha and preparations of opium. *Copaiba*, which is improperly regarded as a balsam, may be exhibited under similar circumstances. It is probable that it acts on the mucous membrane of the bronchial tubes, in nearly the same manner as on that of the urethra in gonorrhœa, by entering the circulation, and exciting a new action on the irritated surface. It is only by admitting that it operates in this manner, that we can account for the benefit which frequently results from its administration in the advanced stages of phthisis.

Among the plants yielding bitter extractive in combination with mucus and fecula, employed as expectorants, we find *marrubium vulgare*, *tussilago farfura*, and *cetraria Islandica*. If the first of these, the horehound, was too much vaunted by the ancients, its expectorant properties have been unaccountably neglected by modern British practitioners. It possesses stimulant powers, alters the state of the bronchial secretion, and seems to impress a new action on the diseased surface; besides promoting expectoration, it diminishes the oppression of the chest, relieves dyspnoea, and improves the digestive function. We have seen much advantage result from its employment in humoral asthma, accompanied with great oppression, and when the sputa was tough, ropy, difficult to be expelled, and causing pain in the expectoration. Many authors, as well as Tralles, have recommended *marrubium* in phthisis. Although we have had no reason to place any reliance on its powers in tubercular consumption, yet we have witnessed much benefit produced by it in that variety of the disease which has been named catarrhal, in which there is much cough, with copious excretion of mucus; a diurnal fever recurring twice a day, nocturnal sweats, and great prostration of strength. In this state the combination of the expectorant and tonic powers found in *marrubium* have proved highly beneficial. The dried plant may be administered in the form of powder, mixed with syrup of white poppies, or in the form of an aqueous or a vinous infusion. The aqueous infusion may be made with $\mathfrak{z}\text{i}$. of the dried plant and a pint of boiling water; the dose is $\mathfrak{f}\mathfrak{z}\text{ii}$. given three or four times a day.

Tussilago farfura, coltsfoot, has been as much neglected as horehound by the moderns, although it held the first rank as a pectoral among the ancients; indeed its name* speaks the estimation in which it was formerly held. Although it has not deserved the praise bestowed upon it by the ancients, yet *tussilago* possesses expectorant properties by no means contemptible. As a gentle tonic expectorant, the writer of this article can bear ample testimony to its influence in the sequel of hooping-cough, when the habit is greatly weakened and the cough continues; and he has seen it equally beneficial in many cases of chronic catarrh. It is best administered in the form of decoction, in making which, care should be taken to strain carefully, as the hairs of the pappus of the flowers sometimes irritate the gullet and excite much uneasiness there. It cannot be prescribed in combination with acetate of lead.

Cetraria Islandica, or lichen *Islandicus*, or Iceland liverwort, or Iceland moss. Notwithstanding the encomiums which have been passed upon it by Scopoli, Hertz, Schneider, Stoll, Wandsorff, Sir Alexander Crichton, and other justly distinguished physicians, it is doubtful whether this plant possesses any ex-

pectorant influence. "In phthisis," says Sir Alexander Crichton, "its good effects consist in improving the matter to be expectorated; in diminishing the frequency of the cough, and rendering it more easy; in calming the irritability of the patient, and in preventing or much moderating hectic fever."* He, however, admits that it did not fulfil his hopes in the cases which he saw treated with it at Vienna; and we have never seen any benefit derived from its use as an article of diet. In preparing it the bitter should not be entirely extracted; as, in that case, it is merely a nutritive substance, well calculated for phthical patients, but possessing no medicinal influence.

Among the inorganic substances of this division of expectorants, *ammonia* and its carbonate are admirably adapted to free the bronchial system from the load of mucus which oppresses it, after attacks of acute pneumonic inflammation in debilitated habits, especially when the expectoration suddenly stops and suffocation is threatened. They operate by the influence which they exert on the nervous system, without augmenting, in an equal ratio, the action of the heart and arteries. The dose of both preparations must be regulated by circumstances: that of the carbonate may be carried to gr. x. or even gr. xv., and repeated every second hour until the effect is produced; after which the dose should be diminished and the intervals extended. Owing to the heat of fauces which it causes in the act of swallowing, it should be involved in some mucilaginous substance, such, for instance, as a combination of the compound powder of tragacanth in almond emulsion.

b. The general expectorants which affect the pulmonary excretories by the nausea which they induce, are few in number. In attempting to explain their mode of operating, we must take into consideration the similarity between the function of the skin and that of the mucous membrane of the bronchial tubes. Both are exhalant organs; and both, in febrile and inflammatory states of the system, are liable to suffer constriction capable of impeding their exhalant function, and giving origin to a train of symptoms depending on a deficiency of the natural lubricating mucous secretion. In this condition of the mucous membrane, antimonials and nauseating remedies relax this constriction, and enable the secretion to proceed; but still it may be demanded—in what manner do such nauseants promote expectoration? It is probable that, during the state of constriction of the bronchial exhalants, any mucus then existing in the air-tubes is of a very acrid character; but as it remains adherent, it excites no effort for its expulsion: when, however, the constriction is relaxed, and it becomes diluted and moveable, it still remains sufficiently acrid to stimulate the glottis and larynx, and thus to call into sympathetic action the whole set of re-

* *Tussilago* is a compound of *tussis* and *ago*.

* London Medical Journal, vol. x. p. 229.

spiratory muscles requisite for the effort of coughing, to expel the now loosened mucus. This explanation is not completely satisfactory: it explains the mode in which the viscid mucus is diluted, but not well that by which it is expelled.

Among the antimonials, the *precipitated sulphuret* was formerly much employed in asthma and chronic catarrh, but the uncertainty of its operation has greatly narrowed the chances of its influence proving beneficial; and as tartar emetic answers every indication, it is now generally preferred. For expectorant purposes, tartar-emetic is given in minute doses; for instance, from one-tenth to one-fourth of a grain, repeated at short intervals. In order to secure its expectorant effect, the surface of the body should be kept moderately warm. It is sometimes combined with squill and other vegetable expectorants; but these combinations improve neither the powers of the tartar-emetic, nor those of the other matters with which it may be combined. Its influence, however, is augmented by the addition of opium, which has been erroneously supposed to diminish the bronchial exhalation; on the contrary, it not only aids other expectorants, but promotes it when given alone: an effect which is to be attributed partly to its increasing the natural secretion of the mucous membrane, partly to its sedative property diminishing the irritability of that membrane.

Before closing this article, it is necessary to offer a few remarks on the circumstances which should regulate us in our selection of expectorants. The first object is to ascertain the nature of the cough, whether it be connected with a state of inflammatory action in the pulmonary organs, or with one of debility; and in that case, whether it be kept up by nervous irritation. In every pulmonary disease attended with cough, there is reason for thinking that the early symptoms are those of inflammation; at that period, therefore, expectorants are of little value, except as auxiliaries in bringing on a crisis; but after the inflammation is partly subdued, then the most salutary effects are obtained from expectoration. In this stage of the disease, the nauseating expectorants are to be preferred; but when the inflammatory action is wholly subdued, those stimulating substances which we have described as calculated to produce the expiratory effort necessary to throw off the load of mucus with which the lungs are oppressed, are then required. It is easy to conceive that thickened or, as they are termed, well concocted sputa, which are generally sufficiently glutinous to adhere together in masses, will be more easily detached and ejected by coughing than a thin mucus, whether accumulated in the tubes, or spread out upon their sides. The necessity, therefore, of ascertaining whether the disease be one of excitement or debility is essential: it is necessary, also, to take into consideration the period of the attack, whether it be the commencement, middle, or termination, when we are called upon to pre-

scribe; for although each of these periods may be benefited by expectoration, yet the substances employed to effect this require to be very different in their characters, according to the period in which they are given. In illustration of this point, we have only to take as an example a case of pneumonia. In the commencement of the attack the bronchial tubes are comparatively dry; but if this state be overcome, either by the use of the lancet, or by a tendency to a spontaneous crisis, the quantity of mucus is then preternaturally increased, and is often tinged with blood. The most favourable symptom in this state is a free expectoration; the most unfavourable, the sudden cessation of it. Our object, therefore, should be to aid this effort of nature, or to produce an artificial state resembling it; not with the view of throwing off morbid matter, but upon principles of a sounder pathology. In the commencement of the attack, if there be any reason for endeavouring to promote expectoration, it must be effected by the gentlest means; such, for instance, as the inhalation of warm aqueous vapour, or by nauseating doses of *ipeacacuanha*, tartar-emetic, and opium. Full vomiting, in this state of the chest, is also, occasionally, highly beneficial; and although, on a *prima-facie* consideration of its mode of action, it may seem at variance with the means just recommended, yet, by favouring a transfer of action, it often induces an increased secretion of mucus from the pulmonary exhalents, productive of the most marked relief. To effect this benefit, however, the vomiting must be full and maintained for a specific time, certainly not less than an hour. If, notwithstanding the employment of these means, the expectoration become too abundant, so as to obstruct the free entrance of the air into the lungs, then the stimulating expectorants are indicated, squill, ammoniacum, the balsams, ammonia, and the topical application of the expectorant gases.

The nauseating expectorants are equally indicated in the commencement of catarrhs, especially in the epidemic variety termed influenza. After bleeding moderately, and the administration of an emetic, the best results have followed the employment of small doses of *ipeacacuanha*, in combination with squills and opium; but when the febrile symptoms have disappeared, and cough attended with a thin frothy excretion only remains, the balsams, gum-resins, and opium, administered in the evening and at bed-time, prove generally highly beneficial. The same precautions are requisite in the administration of expectorants, in the commencement and in the advanced stages of phthisis. In the greatest number of cases of asthma of a recent date, some degree of inflammation is present; but from the progress of the paroxysm, and its termination in expectoration, an erroneous notion was entertained that the solution of the paroxysm must necessarily follow its appearance; and, consequently, squill, ammoniacum, and other sti-

mulant instead of the nauseating expectorants were inconsiderately prescribed, and often produced injurious consequences. In that variety of asthma, however, which appears to depend on a state approaching to that of paralysis of the system of the par vagum, in which the bronchial cells, being deprived of their nervous energy, do not contract sufficiently to aid the expulsion of the air in expiration, and, instead of aiding, prevent the necessary change of the blood in the pulmonary circulation, the nauseating expectorants prove hurtful, by keeping up that state of diminished excitability which is the result of the morbid condition of the bronchial nerves. It is in such cases, and in the low stage of pneumonic inflammation, when the febrile symptoms assume a typhoid character and the lungs are loaded with mucus, that the inhalation of the expectorant gases, the internal administration of the balsams, and more especially of ammonia, prove undoubtedly beneficial.

Under all circumstances there are three general rules to be kept in view in administering expectorants:

1. The surface of the body should be kept moderately warm, and even in a gentle or breathing perspiration.

2. Whatever determines to the kidneys must be avoided.

3. Purging is not only not to be promoted, but to be most carefully guarded against; for as the action of the secreting vessels of the lungs and those of the intestines are opposed to one another, expectoration is checked when purging occurs.

(A. T. Thomson.)

EXPECTORATION.—This word (from *ex* and *pectus*) strictly signifies the *act of discharging* any matter from the chest, but by a figure of speech it is also commonly applied to the *matters discharged* from the lungs and air-tubes.

The act of expectoration is one of the instances of combined movement in the respiratory machine, which, by an admirable and harmonious consent between its numerous muscles, unerringly produces such a variety of actions. The function of respiration is of such vital importance that accumulations or effusions which obstruct it endanger life itself. The structure of the bronchial tree contributes greatly to the easy removal of any superfluous matter in it that might cause such obstruction, for the sum of the area of its branches being considerably greater than that of the trunk, or of the trachea, the air commonly finds easy entrance into the air-cells, and, on its more rapid return in expiration, carries with it the superfluous matter. Thus, ordinary respiration tends to prevent, in spite of gravitation, any accumulation in the air-tubes; but the excretion is more completely effected by coughing, and special efforts of expectoration. These consist of a quick and forcible expiration, preceded by a deep inspiration, and accompanied with a constriction of the larynx and trachea,

the effect of which is to bring any superfluous matter into positions from which the air, forcibly expired, drives it through the glottis. It is worthy of remark that expectoration cannot effectually take place without a previous full inspiration, by which air is carried beyond the accumulating matter; hence, when this is prevented, either by weakness of the respiratory powers, or by the impermeability of the bronchial tubes, the excretion is suppressed. The first of these causes of obstructed expectoration is exemplified in adynamic fevers, which may thus prove fatal: the second occurs in pneumonia in the stage of hepatization, and, if extensive, must lead to a fatal obstruction of the respiratory function. They probably occur together towards the fatal termination of bronchitis, phthisis, and other severe diseases of the lungs.

Expectoration in its other sense, namely, the matter expectorated, is a subject well worthy of a careful study; for its characters often furnish signs of the greatest value in the diagnosis, prognosis, and treatment of diseases of the chest. It can scarcely be said that the examination of the sputa is entirely neglected in this country; but we have had frequent occasion to observe that opinions are very loosely and vaguely formed from it, and of a nature quite inconsistent with the present state of pathological science. Thus the presence of pus in the expectoration is frequently looked upon as a sure proof that the lungs are "diseased;" whilst the far more pathognomonic sputa of peripneumony and the well marked secretion of acute bronchitis are hardly recognized.

The natural secretion of the bronchial mucous membrane is a colourless liquid of somewhat glutinous quality, like a thin solution of gum arabic. It does not greatly differ in chemical composition from the serum of the blood, and it owes its viscosity to an animal substance, which Dr. Pearson,* Dr. Bostock,† and Berzelius‡ concur in considering an imperfectly coagulated albumen. This secretion is the basis of most of the varieties of expectoration; but, unhappily, our knowledge of animal chemistry does not enable us to discover the precise nature of the changes in composition which produce these varieties. All that we learn is that albumen, in different forms and proportions, is present; for, whether the expectoration be mucus, serum, pus, tuberculous matter, or coagulated lymph, the chemist can discover in these but scarcely discernible varieties of this same principle. There seems to be a considerable variation in the proportion of saline matter in different kinds of expectoration; and on this depends a distinction, formerly much insisted on, by means of the salt or sweet taste. This criterion certainly fails in distinguishing pus from mucus; but we think that an excess of saline matter may be taken as a sign of inflammatory action in

* Phil. Trans. 1809.

† Elementary System of Physiology, vol. ii.

‡ Annals of Philosophy, vol. ii. p. 382.

the mucous membrane. It is by its mechanical and visible conditions, however, that expectorated matter is most distinctly characterized; and to examine these fairly, the entire sputa should be collected in one or more convenient vessels of white ware or glass, in which their quantity, colour, and consistence, can be minutely scrutinized.

In acute bronchitis there is at first a diminution of the natural quantity of the bronchial mucus, with a sense of roughness and dryness in the larynx and trachea; but soon a saltish liquid is secreted, which increases as the inflammation reaches its height. It is transparent, almost colourless, and moderately viscid, resembling raw white of egg diluted with water. It generally retains a good many air-bubbles within it, and if expectorated with much coughing, it is usually covered with a froth. When poured from one vessel into another, it falls in a stringy or ropy stream. Andral* considers that its viscosity is in proportion to the intensity of the inflammation; an increased viscosity being always accompanied with an aggravation of the fever, dyspnoea, and other symptoms. When the bronchitis is attended with fever, he remarks that the sputa become more viscid during the febrile exacerbation; insomuch that one inexperienced might be led to suppose that the inflammation had extended to the parenchyma of the lung: after the paroxysm, however, they return to their former state. At the height of the inflammation, and at other times when the cough is violent, they are sometimes streaked with blood: this is produced by the efforts of coughing, and does not tinge the whole mass. These characters are sufficient to distinguish the expectoration of bronchitis in its first stages; and as long as it remains in this state, there is no improvement of the symptoms; but when the sputa become pearly or opake, or of a yellow or greenish-white appearance, we may be pretty confident that the inflammation is on the decline. This opacity is first perceived in the morning expectoration, and in a few points only; and it is uniformly accompanied with an amelioration of the symptoms. The evening exacerbation sometimes brings back the glairy transparency of the secretion; but, unless there be relapse, the opacity returns on the succeeding morning, and gradually extends to all the expectoration, which is then nearly opake, and greenish or yellowish white: the smoke and dust in the respired air sometimes communicate a grey or dirty tinge. This change is often remarkably conspicuous after the successful operation of a sudorific; and, in fact, free perspiration will sometimes partially accomplish it early in the disease. After the expectoration has thus become ripened or concocted, it is coughed up readily, and in loose distinct pellets, which, although glutinous in themselves, do not so readily unite into one mass as before; they gradually diminish in quantity, and in a corresponding degree the cough and other sym-

ptoms cease; a relapse is equally marked by a return of the expectoration to its glairy transparent state. Sometimes a cold is prolonged by a series of relapses; and, notwithstanding the length of its duration, the sputa retaining the same character, the affection preserves its chronic form, and does not terminate until the same change has taken place. These successive transitions, which were noticed by Hippocrates and Aretæus, are highly useful to the practitioner in discovering to him the state of the disease, and, taken with the pulse and physical symptoms, will safely guide him in the employment of his remedies.

The expectoration in chronic bronchitis is of a very diversified character, and is therefore much less certain in its indications. There is generally in it, opake, yellowish, or greenish-white mucus, like that expectorated at the termination of the acute disease; but it is usually more diffuent, and often floats in a pituitous or serous liquid. The same mucus is sometimes voided in a more inspissated form. Andral describes it as resembling false membranes, and moulded into the shape of the bronchial ramifications; and Dr. Cheyne* and Laennec give accounts of a similar expectoration. In the milder cases the mucus thus modified constitutes the whole expectoration; but in a severer form of the disease purulent matter is added, and the appearance, consistence, and odour of the sputa present very great variety.

Many tests have been devised to distinguish pus from mucus; but from what we have before remarked on the close similarity of their chemical composition, it may be judged that they pass by insensible gradations into each other. The utility of minute distinctions of this sort may therefore well be questioned, as they neither enlighten us on the pathology, nor guide us in the practice. Pus is much less viscid than mucus, and not retaining air-bubbles, as mucus does, it commonly sinks in water, whereas mucus generally floats at the surface; and this test gives us as much as is useful in the distinction. When the two are mingled in various proportions, this and all other tests fail in discriminating them. Proceeding from different parts of the bronchial membrane in different degrees of inflammation or morbid affection, some portions of the expectoration are mucous and viscid, whilst others are purulent and diffuent; some greenish-white like pus; others grey, dirty-looking brown, or tinged with blood: generally they are inodorous, but sometimes they exhibit a remarkable fetidity. These characters, however varying, are unquestionably diagnostic signs of chronic inflammation of the bronchial membrane; but their value in the prognosis and in practice is greatly diminished by the circumstance of such chronic inflammation being frequently complicated with other lesions. It almost always, for instance, accompanies the last stage of tubercular dis-

* Pathology of the Membrane of the Larynx and Bronchia. p. 147.

* Clinique Médicale, tom. ii.

ease in the lungs, generally furnishing a great part of the matter expectorated; and its existence is of small importance compared with the phthisical lesion. An inspection of the expectoration alone often fails to distinguish these combined cases from those of simple chronic bronchitis. In general, it may be said that purulent sputa indicate a severe form of disease; but they neither necessarily imply phthisis, nor any other irremediable malady. The chronic bronchitis excited by habitual inhalation of dust or powder, as among needle-pointers, leather-dressers, porcelain-makers, &c. is commonly attended early with purulent and bloody expectoration; but if the cases are treated in time, and the patients are removed from the continued application of the exciting cause, they generally recover. So also, severe cases succeeding to measles and scarlatina sometimes present purulent expectoration, yet they are far from being universally incurable. We repeat, therefore, that puriform matter in the expectoration, as a prognostic sign, only indicates an aggravated form of disease.

The nature of the expectoration gives the distinctive characters to the diseases termed by Laennec dry and pituitous catarrh. The former is a kind of asthma, attended with no other expectoration than scanty pellets of very tough grey mucus, which lodge in the bifurcations of the bronchi, and sometimes cause severe fits of asthma. It is important to recognize the expectoration of this disease, as it is singularly benefited by the alkaline treatment recommended by Laennec. Pituitous catarrh, or humoral asthma, is remarkable for the profuse watery expectoration which accompanies its paroxysms. This discharge contains albumen, coagulable by heat, and seems to differ but little in nature from the serum of the blood. Its quantity is sometimes enormous, amounting to several pounds in weight. These two forms of secretion sometimes occur at the same time in different portions of the bronchial membrane; and the serous discharge, in smaller quantities, is a common accompaniment of chronic bronchitis.

The expectoration of pneumonia is very characteristic. For the first two days there is seldom any expectoration; but, about the third or fourth, a viscid transparent liquid is spit up, uniformly tinged with a rusty or orange hue. At first its viscosity is not so great but that it can be poured from one vessel into another, and it falls in strings or ribands; but in proportion as the inflammation reaches its height, and passes to the stage of hepatization, it becomes so glutinous that the vessel may be inverted, and even shaken without its falling. The red tinge is generally proportionably increased, but this is a less certain test than the viscosity, of the intensity of the inflammation. If the inflammation declines or is mitigated, the sputa become less viscid and rusty, until they present the characters of the expectoration in bronchitis. It is to be regretted that this valuable and truly distinctive sign does not show itself early and constantly in the disease. When it is present, it may confidently be de-

pended on, but its absence by no means improves the existence of pneumonia. In some individuals it never occurs; and in children it is difficult to obtain a sight of the expectoration. It is also important to know that many adults, like children, invariably swallow the expectoration. The physical signs are, therefore, alone to be depended on in the diagnosis of negative cases. As a prognostic guide the sputa are highly instructive. The unfavourable import of a late appearance of the sputa was noticed by Aretæus; but M. Andral first pointed out the proportion which their viscosity bears to the intensity of the inflammation. As long as this goes on increasing, or remains undiminished, we may be sure that the inflammation is predominant; but if the expectoration shews a disposition to return to the colourless and less viscid state of simple bronchitis, the disease may be known to be on the decline. In a few cases the expectoration increases in viscosity up to the hour of death, but more generally it is either suppressed or changed, particularly if the inflammation have proceeded to the stage of suppuration. The suppression of the expectoration was considered by the ancients an unfavourable omen; modern pathology discovers that it is so, either because it proves the inability of the patient to expel it, or because the secretion has ceased, and the inflammation passed to the hepatized and suppurated stages. In the former case suffocation must soon ensue from the accumulation in the bronchi: in the latter the rusty expectoration is often replaced by other kinds. Sometimes it consists of brownish dirty-looking opaque mucus; sometimes whitish specks, as of pus, are seen in it, and, rarely, it is entirely purulent.

M. Andral describes another kind of expectoration which he considers generally to indicate the stage of suppuration. This is a deep reddish-brown and slightly viscid liquid, like the juice of preserved prunes or liquorice water. In six out of nine cases in which this was observed, the lung was found, on dissection, in the state of purulent infiltration; in two it was hepatized; the remaining case was a slight one, and recovered. Laennec does not attach any importance to this kind of expectoration, considering it only as the sign of a cachectic or scorbutic habit. It certainly cannot be considered distinctive, but it may be taken presumptively, and must generally be looked upon as an unfavourable sign. The tinge of the characteristic peripneumonic sputa, which is, in different instances, greenish-yellow, orange, rust-coloured, and bright-red, obviously proceeds from the colouring matter of the blood, intimately mixed with it in various proportions. If the inflammation terminates in resolution, this tinge diminishes and disappears, and the sputa exhibit the characters, and go through the changes of the expectoration in bronchitis.

In pure pleurisy there is either no expectoration, or one simply of a catarrhal nature. The fluid secreted in chronic pleurisy has been sometimes known to make its way into

the bronchi, and to be evacuated by expectoration; but other signs must rather be depended on for discovering the nature of such a case; as a similar expectoration is sometimes derived from a pulmonary abscess, and even from sudden and copious secretion from the bronchial lining only.

The character of the sputa has been more consulted in the diagnosis of consumptive diseases than in any other; but the advances which have of late been made in developing the true nature of tubercular phthisis, have proved that all the distinctions and tests proposed are more or less fallacious. Thus it was long held that the presence of pus in the expectoration was a pathognomonic sign of pulmonary consumption; and all efforts were directed to find out a sure method of detecting it and of distinguishing it from mucus. We have already remarked that purulent expectoration is not an uncommon consequence of simple bronchitis, and this disease presents all the phases formerly ascribed to phthisis. Something of the prognosis may, we believe, be learnt by consulting the expectoration, but its distinctive characters are to be depended on only after repeated examinations, and in combination with other signs, particularly those of auscultation.

In the first stage of phthisis, that of miliary tubercles, there is either no expectoration, and the cough is dry, or it is of a simple bronchitic nature. When the lungs are thickly studded with miliary tubercles, there is not unfrequently an abundant serous secretion like that of pituitous catarrh, which is accompanied with a constant and general mucous rhonchus in the lungs. Whenever these present themselves for any length of time in an individual of tuberculous diathesis, and especially if there be any irregularity of resonance on percussion about the clavicles, we consider the fate of the patient almost certain, and the disease will probably run a very rapid course. Except in this case, and in that of hæmoptysis, which is treated elsewhere, (see PULMONARY APOPLEXY and HÆMOPTYSIS), the expectoration does not assist us in the first stage of phthisis.

The characters of the sputa in the second stage, or during the softening and evacuation of the tubercles, would be much more distinctive were they not almost always mixed up with the mucous and muco-purulent secretion of a chronic bronchitis, which always more or less prevails at this period. Hence the signs, as relating to the tubercular disease, must be considered in a corresponding degree ambiguous. Attentive examination will often discover in the mucus expectorated fine whitish streaks, which consist of the softened tubercle; more rarely there are little yellowish white masses like grains of boiled rice, which are portions of crude tubercle. As the softening proceeds and the cavities are enlarged, the sputa become less frothy, sink in water, and are principally composed of greenish white masses of irregular shape and outline, sometimes tinged in parts of a dirty red or brownish colour,

These flatten at the bottom of the vessel like a piece of money, whence they have sometimes been called *nummulary* sputa. In some rare instances small portions of the pulmonary tissue itself have been detected with the preceding. When the disease is further advanced, the expectoration assumes a brown, dirty green, or grey colour, and the sputa are frequently surrounded with an areola of a bloody tinge. It is exceedingly difficult to say what degree of weight should be attached to these several appearances, even when they are unequivocally seen. It might be supposed that the presence of the whitish streaks or of the little white masses would be conclusive, as being themselves tubercular matter; but appearances of the same kind may present themselves from other sources. The minute bronchial ramifications, in chronic inflammation, sometimes secrete a purulent liquid, which may produce the same streaky appearance; and vermicular concretions and filaments of yellowish white lymph formed in the same way may be mistaken for little fragments of tubercle. The little rice-like bodies, which were considered by Baglivi, and Bayle, and even by Hippocrates, as indications of phthisis, are moreover closely simulated by certain sebaceous concretions formed in the tonsils, and, according to Andral, by similar productions from follicles in other parts of the pulmonary mucous membrane. The white matter from the tonsils may, however, be always distinguished, as Laennec has pointed out, by their fetid odour and by their greasing paper when heated; and without attention to this test, the sign cannot be depended on. The globular yellowish white masses, like irregular balls of flock or wool, which apparently consist of pus held in shape by a little tenacious mucus, have been noticed by several writers as peculiar to phthisis. Dr. Forbes* says that this kind of expectoration has appeared to him to be most common in young subjects of a strongly marked strumous habit, and in whom the disease was hereditary. A precisely similar appearance is, however, sometimes presented by the sputa in chronic bronchitis. The dirty brown or green matter, flattening and becoming nummular when separate, and when together forming a smooth sluggish *purilage*, which appears later in the disease, and takes its origin from the tubercular excavations, is much more certainly characteristic of phthisis. To sum up, we may say that an *occasional* examination of the sputa, by far the greatest part of which, as Laennec has remarked, proceeds from an accompanying bronchitis rather than from the tubercular disease itself, can only enable us to distinguish phthisis in the very rare case of tubercular matter, or portions of the tissue of the lung being present: but, with Dr. Forbes and M. Andral, we think that by a daily careful inspection of the expectoration, we shall not fail to find in the successive and progressive changes which it presents, the means of forming a pretty

* Transl. of Laennec, 3d edit.

accurate diagnosis, which, if confirmed by the general and physical signs, will leave no shadow of doubt.

As our design in this article has been rather to direct the attention of the practitioner to the importance of expectoration as an aid in diagnosis and prognosis than to give a complete account of the subject, we refer for further descriptions to the articles in which the diseases of the chest are particularly treated of.

In conclusion, we would strongly recommend our readers to consult the second and third volumes of Andral's *Clinique Médicale*, and Dr. Forbes's translation of Laennec's *Auscultation Médiate*, where they will find instructive and convincing proof of the assistance which the expectoration gives, especially if taken in conjunction with the physical signs, in the distinction and treatment of diseases of the chest. (C. J. B. Williams.)

FAVUS. The pustules termed *favi* are so named from the character of the crusts by which they are succeeded; these being cellular, and fancifully compared to an irregular *honeycomb*. The term *favus*, however, was differently employed by the ancients: Galen applied it to ulcers which exude, through small orifices, a matter resembling honey in consistence; Celsus regarded it as synonymous with *miliary*. *Favi*, in the modern acceptance of the word, are small, yellow, irregularly circular pustules, nearly flat, at least not acuminated; and, according to Biett, always depressed in the centre. Their base is slightly inflamed; they generally appear in circular patches or clusters; are attended with itching, and frequently with glandular swellings from absorption of the matter. These pustules are succeeded, after some days, by a thick yellow, nearly semi-pellucid, somewhat cellular, augmenting crust or scab; at which time they frequently exhale a very offensive, nauseating odour, not unlike that of the urine of a cat. As the crusts dry, they become white, and easily detached.

The seat of *favi* is most commonly the scalp, in the epidermal layer which covers the papillæ of the true skin. As they most commonly occur on parts covered with hairs, Dr. Duncan advanced an opinion that the disease is in the bulb of the hairs, which are indeed easily detached, and display a swelling at the base. Biett accords with this opinion; but Rayer dissents from it, and supports the view which we have adopted.

Favi generally occur during childhood; they seldom affect the general health, although, when they appear during the period of dentition, they seem to be in a great degree connected with the disordered state of the digestive organs which more or less attends that period, and the increased irritability of the habit. They occasionally, however, appear in adults, on the neck, ears, and occiput: in these cases they are always preceded by some degree of constitutional derangement; headache, an uneasy state of stomach, loss of appe-

tite, irregular bowels, and fever: the inflammation surrounding the pustules is more extensive, and the crusts are thicker and harder than in childhood. Alibert affirms that cooks are very liable to eruptions of *favi*. They are chiefly known as the distinctive feature of one species of porrigo,—*P. favosa*; under the head of which we shall have again to direct the attention of our readers to their characters. Biett* supposes that the minute pustules of porrigo *scutulata*, which appear in circular patches, are *favi*, differing only in their arrangement and some little variation in the state of the crusts; but as far as we are enabled to form an opinion by the appearances which they present, when viewed with a powerful magnifier, the opinion of Bateman,† who regards them as *achores*, is correct. Rayer‡ considers both the pustules and crusts intrinsically different from those of porrigo *favosa*.

As we shall have again to detail the treatment of *favi* under the article porrigo *favosa*, we have only to mention, at this time, that it consists in correcting the irritable state of the stomach, and in not permitting crude undigested matters to remain in the alimentary canal. This is best effected by moderate doses of hydrargyrum cum creta, combined with antimonials, administered at bed-time; and alkaline salts, particularly subcarbonate of soda, in combination with calumba, or cascarrilla, or cinchona bark in powder, given twice or three times a day. It was the opinion of Ætius and other old writers, that danger attended the repulsion of *favi*: modern practitioners, regardless of this, employ a variety of external applications; but these are general mild stimulants, intended rather to restore the healthy action of the skin, after the crusts have been removed by poultices, than to repel. They consist of ointments composed with the oxides of zinc, acetate of lead, and tar with sulphur; and the ointment of nitrated mercury largely diluted with simple cerate. When there is much itching or pain, the writer of this article has seen great benefit derived from the following lotion, applied in a tepid state, in the form of a poultice.

R. Liquoris plumbi subacetatis, *f* 3i f3.

Acidi hydrocyanici, *f* 3ii.

Aquæ distillatæ, *f* 3vi. M. Fiat lotio.

Cleanliness, exercise in the open air, and the stimulus of soap and hot water, are great aids to every method of treatment. Much depends on diet, which should be apportioned both in quantity and quality to the powers of the stomach and the general strength of the patient. If the patient is weak, which is generally the case, the food should be nutritive, but not stimulant: we have found nothing answer better than milk, with a moderate allowance of plainly cooked mutton or poultry

* Abrégé pratique des Maladies de la Peau, par MM. Cazemene et Schedel, p. 231.

† Synopsis, edit. 7th, p. 138.

‡ Traité théorique et pratique des Maladies de la Peau, par P. Rayer, vol. i. p. 520.

once a day. Wines and all kinds of fermented liquor are injurious.

Favi appearing under the form of porrigi favosa are contagious; and it is probable that they are equally so when they suddenly appear as symptomatic of derangements of the stomach and chylopoietic viscera; but we have seen no positive demonstration of their contagious nature under these circumstances.

(A. T. Thomson.)

FEIGNED DISEASES. It is our intention to notice under this head all that class of alleged corporeal disabilities which are either pretended or intentionally induced. In strictness of classification, cases of this kind should be arranged in four groups:—

1. Feigned diseases, strictly so called, or those which are altogether fictitious.

2. Exaggerated diseases, or those which, existing in some degree or form, are pretended by the patient to exist in a greater degree or different form.

3. Factitious diseases, or those which are wholly produced by the patient, or with his concurrence.

4. Aggravated diseases, or those which, originating in the first instance without the patient's concurrence, are intentionally increased by artificial means.

It is not, however, our intention to adopt this classification in the present article. We shall arrange all the diseases under one head, and in alphabetical order; this method being more simple, more in accordance with the general plan of this work, and affording greater facilities for practical reference. We may also here observe, that, for reasons of convenience, we shall apply the term *feigned* to all the varieties of these disabilities.

The following are the classes of persons by whom diseases are chiefly feigned, and the causes of their being so:—

1. Men apprehensive of being levied, or actually levied, or forced into the military or naval services: conscripts; men liable to serve in or to be drafted for the militia; impressed seamen. The cause of diseases being feigned by such persons is the hope of being deemed unfit for the duties of the public service, and thus to escape it altogether.

2. Soldiers, and seamen in the navy. The causes which induce these persons to feign disease are chiefly the following:

a. To obtain their discharge from the service, with or without a pension.

b. To avoid the performance of the duties imposed on them; to escape some particular service that is disagreeable to them, or to obtain some other that is agreeable; to obtain a removal from one climate or station to another; to obtain the ease and comfort of an hospital, &c.

c. To avoid an apprehended or adjudged punishment.

Soldiers and sailors feigning disease are commonly designated as *malingers* or *skulkers*. The latter term is exclusively used in the navy.

3. Slaves. These unhappy persons feign

diseases from many of the motives which influence the soldier and sailor, whose services are compulsory; only they do not seek for a permanent discharge from their labours, which they know to be impossible, except indeed by death. Their chief objects are to obtain relief from labour, and to enjoy the comparative comforts of the hospital.

4. Persons who have subjected themselves to the control of the laws, and are either undergoing punishment or in apprehension of it; persons about to undergo a trial for some alleged offence, or about to be punished for the same; prisoners for debt, or other offences, civil or criminal. The motives of such persons for feigning diseases are sufficiently obvious, viz. to evade or escape punishment or restraint.

5. Persons in civil life who have received slight injuries, and who greatly exaggerate their degree or consequences. This is generally done with the view of extorting a disproportionate compensation from the party injuring.

6. Persons in the lower ranks of life desirous of exciting the attention and compassion, and consequently the bounty of the public, or a maintenance in idleness. This class comprehends the professed mendicant, whether vagrant or stationary, whether gipsy or gentleman-beggar; and also persons in the lower ranks among the poor, who occasionally in this manner practise on their richer neighbours. Under this class, also, come persons in the lower ranks of life who wish to obtain relief from benefit societies, or from the parochial funds, or to gain admittance into or to remain in workhouses, hospitals, &c.

7. Persons not at all in poverty nor living in a constrained position, who assume the semblance of disease from some inexplicable causes. These are chiefly females; but the class is on the whole very small.

We might add to these, other classes from various conditions of life, from the boy "creeping like snail unwillingly to school," up to kings, warriors, statesmen, and various others in high stations, whom history records as having assumed sickness to gain particular objects;*

* Many great names, illustrative of the statement in the text, might be mentioned. The plan adopted by Ulysses to avoid leaving his young bride for the war of Troy, is familiar to the classical reader. The particular manner in which this royal malingerer chose to exhibit his alleged infirmity, and the mode of its detection, are pleasing illustrations of the rude simplicity of early times. The king goes as usual to his agricultural labours, but not as usual like a sober ploughman; he yokes together in the same plough a horse and an ox, and sows his field with salt in place of corn. With the view of putting to the test his alleged disease, Palamedes places Telemachus in the furrow before the father, who betrays his sanity by carefully avoiding the infant. The history of the feigned insanity or idiocy of the elder Brutus is equally well known; as is that of Amnon the son of David, who "made himself sick" for a more guilty purpose. Charles, Duke of Bourbon, constable of France, wishing to desert to the emperor, "feigned sickness in order to have a pretence for staying behind." (Hume.) In like manner,

———"Hotspur's father, old Northumberland, Lay crafty-sick,"

but the above, we believe, contain nearly all the cases that are likely to come under the notice of the medical practitioner.

Some diseases or disabilities are much more easily feigned than others, and the imposture is more difficult to detect. In those diseases of which the symptoms are naturally obscure, or variable and uncertain, much care should be taken not to come to a wrong conclusion. Every medical practitioner knows that there are some diseases which are not indicated by a change of the pulse, an alteration of the natural colour or temperature of the body, or by any evident derangement of its functions. There are also other diseases the symptoms of which are capable of being imitated by the effects produced by certain drugs, or by the use of certain external applications, &c. An intimate knowledge of the anatomy, physiology, and pathology of the human body, and of the effects of the articles of the *Materia Medica*, is therefore essential to enable the medical practitioner to obviate false conclusions and detect imposture in such cases.

When a medical practitioner is called upon to examine, for the purpose of legal investigation, or to treat a doubtful case of disease, he should endeavour to obtain all the information he can respecting the person's moral and physical habits, his probable motives, &c. &c.; and he should also consider whether the alleged causes of the disease are founded in fact, or are probable. Another important point is, to endeavour to ascertain whether the pathognomonic symptoms of the alleged disease are present. "It is obvious," says Dr. Cheyne, "that the more we know of disease by reading and observation, the more patience and temper we possess, the more successful shall we be in the detection of imposture. I am convinced that simulated disease will soonest be discovered by those who conduct the inquiry in the most scientific manner, carefully applying the case in doubt to the description of the disease in standard works of pathology."*

It is difficult for the simulator of a disease to give a consistent account of the origin and progress of his alleged infirmity. By a little management on the part of a medical practitioner, an impostor will almost always be led to enumerate incompatible symptoms, or greatly to exaggerate unimportant lesions. He is constantly prone to overact his part. He is too anxious to impress upon the medical at-

to avoid the battle of Shrewsbury. Essex, the favourite of Elizabeth, is said to have feigned a violent disease to move her compassion; and Raleigh pretended "madness, sickness, and a variety of diseases to protract his examination and procure his escape." (Hume's James I.) Pope Julius III. feigned sickness to avoid the holding a consistory; "and that he might give the deceit the greater colour of probability, he not only confined himself to his apartment, but changed his usual diet and manner of life." By persisting in this plan, however, he contracted a real disease, of which he died in a few days. (Robertson's Charles V.)—It would be easy to add greatly to the above list from the stores of tradition and authentic history, ancient and modern.

* Letter to Dr. Renny, on Feigned Diseases; Dublin Hospital Reports, vol. iv.

tendant the reality and the severity of his sufferings. Remarks are thrown in purposely to obviate objections, and to reconcile the mind to what may seem extraordinary in the narrative; all of which are very unlike the bold simplicity of truth.

With the view of inducing a detected or even suspected impostor to acknowledge his deceit, severe measures, such as the infliction of pain, &c. remedial agents, and even formal corporal punishment, have been occasionally adopted. This practice, however, if it were justifiable, will be frequently found to fail even in the army or navy, where patients are under the control of strict discipline. But it ought to be a general rule that means should never be adopted in the treatment of a doubtful case which we should regret having employed if the alleged disease were to prove genuine. Soldiers and sailors commonly return to their duty when they are deprived of all hope of succeeding in a scheme of imposture; and finesse will often succeed in detecting imposture where harsh measures would completely fail. Dr. Davies, surgeon to the East India Company's depot at Chatham, had a soldier under his care with an alleged affection of the back, which, the man asserted, rendered him unable to move or be moved from his bed. His alleged disability had existed for about a month without any indication that he intended to return to his duty. For the convenience of being watched, &c. he had been accommodated in a ward by himself. Dr. Davies, who considered him to be an impostor, saw no prospect of his *giving in*; but he eventually put in practice a measure which led to detection. He went to the window of the ward in the dusk of the evening, and after gently tapping upon the glass, he in a low voice called the man by his name. He was at the window in an instant, and Dr. Davies had the pleasure of congratulating him on the recovery of the power of locomotion. The man forthwith went to his duty.

Sometimes impostures are discovered entirely by accident, even when they are not at all suspected to exist. The following is a curious instance of this kind. A seaman on board H. M. ship *Otter* feigned a chronic decline so effectually that he not only deceived his surgeon but the physician of the Naval Hospital to which he was sent; and he was about to be discharged from the service, when the true nature of his case was elucidated in an unexpected manner. The mail from the seaport where the man was in hospital was robbed, and the letters were broken open with the view of searching for money. The robbers were however taken, and the letters recovered. Among the opened letters was one from the man in the hospital to his wife, wherein he informed her that his scheme had succeeded, that he was going to be invalided on a certain day, and desiring her to make good cheer against his arrival. This letter was forwarded to Capt. W., and in consequence of its contents, the man, although seemingly in almost a dying state, was returned to his ship. The

letter being read to him, and his hopes thus destroyed, he at once returned to his duty.

It is frequently useful to depart from the usual mode of examining doubtful cases; pre-concerted plans being thereby disconcerted, and an impostor puzzled. One of the writers of this article was requested to look at an old soldier who had been long in a civil hospital on account of an alleged contraction of the left knee, the real existence of disease being doubtful. The examiner went to the left side of the bed upon which the man was lying, and after looking at the contracted knee he desired the man to lie upon his face, by which change the right extremity assumed the place of the left in the bed. The examiner's hand was then placed upon the *right* knee, which became gradually flexed, while the contraction of the left knee disappeared. This man's attention was so completely engaged with the right knee when it was under examination, that he forgot that it was his left knee which he had alleged to be contracted.

It might be an amusing subject of inquiry how particular diseases come to be assumed in preference to others. Our limits will not permit us to enter upon this investigation. A principal, if not the chief cause, is the relative facility with which diseases may be feigned or formed; some, as we have already observed, being much more easily assumed than others. Imitation of the real diseases which the impostors are in the habit of seeing is also at once a frequent source of their knowledge, and the exciting cause of their putting it to account. We have thus known soldiers and sailors carefully study and mimic numerous ailments of their comrades. We remember the case of a soldier who imitated admirably and successfully the gait of a patient with hip-disease, which he had studied from the life in a boy who actually laboured under that affection.

We know not that any excuse is necessary for the extent of the consideration which we purpose to give to the subject of the present article. Certainly none will be expected by those of our readers who either now practice, or formerly have practised, in the medical departments of the army or navy, who are fully aware of its great importance. If there be any practitioner in civil life who entertains doubts on this point, the facts detailed in the present article will, we think, be found more than sufficient to remove them. And although it is especially in the practice of the medical officers in the public service that cases of feigned diseases occur, yet their occurrence in private practice, particularly among the patients of our hospitals and dispensaries, is by no means extremely rare; and many of them are of such a kind as to expose the knowledge or ignorance of the physician or surgeon more positively and more conspicuously than any other cases. Many of them, also, become the subjects of legal investigation, and require medical testimony to be given in courts of law.

In the army and navy it is the duty of the

medical officers to protect the public service from impositions of this kind; and it is well known to those officers who served during the late prolonged wars, how seriously the service both of the army and navy suffered from such impostures being oftentimes successful. On the decision of the medical practitioner as to the true character of doubtful cases, very frequently depends the acquittal or punishment of the alleged invalid; and every one must feel the responsibility of such a position. It is well known to those who have had opportunities of judging, that men in the army and navy, more particularly the latter, have been often treated and punished as impostors, who were really labouring under disease; and also that real impostors have often received the immunities and privileges that ought to belong only to the diseased. The scene in *Roderick Random*, of the captain and doctor curtailing the long sick-list, is probably only a slight exaggeration of what Smollett may himself have witnessed in the olden time of the navy; and although no such scene could be exhibited now-a-days, it must be allowed that nothing but that firmness of purpose which can alone be founded on the knowledge of disease, will always enable the medical officers in that department of the public service to protect the rights of humanity and the dignity of the profession of medicine.

1. *Abdominal tumour.*—(Ascites, tympanites, physconia).—Various affections of the abdomen characterised by external swelling are often both feigned and formed by persons desirous of obtaining certain objects under the cloak of disease. We have seen dropsy simulated for some time successfully, merely by the individual pushing the abdomen forward while in the erect position, and elevating the spine when lying on the back; probably, at the same time, keeping up the distension by means of very short expirations. A complete exploration of the uncovered abdomen will always detect imposition of this kind. It has been proposed in such cases to observe the patient when asleep; but such simulators are sometimes prepared for this test, and wrap themselves up so completely in the bed-clothes that the end cannot be obtained without awakening them.

A more effectual mode of deceiving is, to distend the abdomen by the introduction of foreign substances. Instances are said to have occurred among the French conscripts where water was actually injected into the cavity of the peritoneum, and a true factitious ascites thereby produced. Foderé mentions the case of a woman who produced a simulated ascites by inflating the cellular substance of the abdominal parietes with air, through a small and scarcely perceptible puncture in the groin.* Manual examination or palpation would immediately detect this kind of deception. Tympanitic distension of the abdomen by artificial means has been more extensively and

* Médecine Légale, tom. ii, p. 485.

more successfully practised. MM. Percy and Laurent mention the case of a young soldier who had the power of distending his abdomen enormously by swallowing air. Presenting himself in this state, with clothes made for the occasion, he had no difficulty in obtaining his discharge. He got rid of his tympany at will, "par le moyen d'eructations bruyantes et non interrompues, par haut et par bas."* The following extract from Dr. Cheyne's excellent paper on feigned diseases, in the fourth volume of the Dublin Hospital Reports, will shew the extent to which this mode of deception is sometimes carried. "In the year 1811, from thirty to forty men of the 84th regiment were admitted into the King's Infirmary, labouring, as stated on the admission-ticket, under dropsy and intermittent fever. The abdomen was greatly distended and felt tympanitic; the tongue, with few exceptions, was clean; pulse regular; urine natural, and bowels in general costive. The men complained of pain in the right side, and many of them of pain over the whole abdomen, with excessive thirst, drinking more than a gallon of water daily. The disease was at first considered a consequence of the Walcheren fever; but, from the numbers increasing, and all with the same symptoms, Dr. Harvey was led to conclude that the complaint was feigned. Under that impression he prescribed a solution of Glauber salts in weak tobacco-water, which he called the *infusum benedictum*; a cupful of this detestable compound was given in the morning, and repeated every fourth hour till it operated, and with perfect success; all who were in the hospital recovered speedily, and the disease, which was becoming epidemical, soon disappeared; however, sixteen had succeeded in obtaining their discharge before this method of treatment was discovered." It was reported that the men produced this artificial tympany by swallowing large quantities of chalk and vinegar. Is this probable?

Simulated dropsy, or other abdominal tumour, is a common deception of mendicants, and is by them usually accomplished by the aid of cushions fitted to the belly. A remarkable case of this kind is related, in the *Act. Nat. Cur.*, of a woman who practised this imposition for forty years, and made a comfortable livelihood by it. No tumour was found on examining the body after death, but a pad found in her wardrobe, weighing nineteen pounds, and fitted to the shape of the abdomen, explained the case. A man not long since obtained his living in Edinburgh by the same means; on being detected he enlisted as a soldier.

Abstinence, partial or total.—Abstinence for a great length of time is sometimes feigned in order to excite public curiosity, and, consequently, commiseration and charity. Abstinence beyond a moderate period is contrary to the usual course of nature, and therefore strong suspicion may always be entertained when extraordinary fasting is alleged. The most noted

imposture of this kind in recent times is that of Ann Moore, the fasting woman of Tutbury. According to her own account she fasted from March, 1807, for a period of six years. She certainly fasted for nine days and nights.* For numerous references to similar cases the reader is referred to the *Litteratura Medica* of Ploucquet, art. *Inedia*.

3. *Animals in the stomach.*—Mendicants occasionally allege that they have an animal in their stomach. There was a man not long since in Edinburgh who was remarkably successful in deceiving the public by pretending that he had such an inmate, which he said occasionally came to his throat, a statement he attempted to corroborate by making the most frightful grimaces. It may be mentioned, as in some degree illustrative of the means of deception in such cases, that one of the writers of this article has now under his care a patient affected with partial obstruction of the pylorus, who has the power of producing the most extraordinary noises in his stomach by throwing the abdominal muscles into strong action. The stomach is no doubt enlarged, and as it generally contains an immense quantity of liquid and also much air, the sounds are occasioned by the rapid commixture of these fluids of unequal density. There is a case recorded in the 9th volume of the Edinburgh Medical Journal, which is remarkable inasmuch as Dr. Spence, the reporter, details the circumstances as gravely as if he had no doubt of the fact. A woman, twenty-one years of age, having been indisposed for a few days, took some cathartic medicine, and passed by stool "a reptile of the *lacerta* species." The animal, of which a particular description is given, on the sole authority of the patient, is stated to have been between four and five inches long, and considerably thicker than a finger.

4. *Blindness, total or partial.*—This disease is frequently feigned by wandering beggars, and also by men in the military and naval service. The most common form of assumed blindness is amaurosis; but at other times paralysis of the eye-lids, producing blindness by preventing the access of light, is the alleged disability, and in this case an artificial ophthalmia is often induced at the same time. In feigned amaurosis, if the simulator is skilful and courageous, the deceit is with the more difficulty detected, because in true amaurosis there is sometimes a certain degree of motion in the iris. A remarkable case of pretended blindness is related by Mahon, in which the patient was placed on the steep bank of a river and desired to walk forward. He unhesitatingly did so, and fell into the stream. This test was considered as a proof of the reality of the disease; but he was afterwards induced, on a promise of being discharged the service, to confess that the disease was feigned.† In this case the pupil contracted perfectly; and although this may be no certain proof of soundness of the organ, it is

* Dict. des Sc. Méd. t. xli. p. 328.

* Edin. Med. Journ. vol. v.

† Méd. Légale, tom. i. p. 366.

perhaps fair to admit immobility of the iris on exposure to light as a sign of disease. In the following case the deception was equally complete, but the detection came from a different quarter. A seaman on board the *Utile* frigate, pretending to be totally blind, and believed to be so, was on one occasion permitted to go on shore, and was attended by a man to lead him about the streets. These two happened to quarrel, and even came to blows, when the blind man finding, as might be expected, that he was likely to have the worst of the fray, suddenly regained the use of his sight, and soon got the upper hand of his astonished guide. The latter being worsted, took to flight, was pursued through a great part of the town by his former protégé, and, finally, received a severe beating from him. Next day the impostor was severely flogged, and never afterwards exhibited any deficiency of vision.

Blindness under the form of amaurosis used to be simulated to a great extent by the conscripts for the French army, and for some time with the desired effect. A dilated pupil and an inactive iris, the leading symptoms of this disease, may be induced by the extract of belladonna, the substance supposed to have been employed. When a sufficient length of time is permitted, the means of detecting this fictitious amaurosis are obvious. It has been stated by good authority that two hundred conscripts were exempted from serving in the army by using belladonna.

Intermittent blindness (nyctalopia, hemeralopia) is much more frequently and successfully feigned by soldiers and sailors, more especially in warm climates, where the real disease is of very frequent occurrence. In tropical countries night-blindness occasionally prevails among Europeans epidemically, and hence arise at once the source of the imposture and the difficulty of detecting it. Night-blindness is a common disease in Egypt, and was frequently feigned by our soldiers in the expedition under Abercrombie. "Of some corps," says Dr. Cheyne, "nearly one-half of the men were affected with this complaint, or pretended to be so, for which, however, a remedy was soon found. In the parties engaged in the works, a blind man was joined to and followed one who could see, in carrying the baskets filled with earth; and when the sentries were doubled, a blind and a seeing man were put together, and not without advantage, as during the night hearing upon an outpost is often of more importance than sight."^{*} In tropical climates sailors frequently feign this disease with the view of escaping night-duty. It is hardly possible to detect the imposition by mere symptoms, as in the real disease the aspect and functions of the eye are perfectly natural in full light.

5. *Cachexia, malacia, or pica Africanorum.* (Mal d'estomac, dirt-eating.)—This is a disease which often produces the most extensive ravages among the slaves in the West-Indies, carrying them off slowly, but with the certainty of a pestilence. It is not nearly so common

now as formerly, negroes being much more valuable to their masters, and better treated. It is often a real disease, but it is often, also, a practice voluntarily adopted by the unhappy beings who are the subjects of it, with the object and with the effect of producing death. Still more frequently, perhaps, it is a mixture of real and factitious disease, the primary disorder of the stomach prompting to the ingestion of crude substances, and thus giving the particular direction to the suicidal propensity. Whether it exists as an irresistible propensity, or is adopted as a means of producing disease, the practice of dirt-eating is always done in secret, and is invariably denied. All kinds of earth are eaten indiscriminately, such as the common soil or mould, and the plaster of houses, &c. The disease produced is truly a cachexia, marked by disorders of various functions, diminution of the colouring matter of the blood, &c. and terminating in general dropsy. The patients first complain of pain of stomach (hence its French name), then breathlessness, and inordinate pulsation in the heart and large arteries, particularly of the carotids and aorta, on motion. They become bloated, their nails and the palms of their hands becoming white, and their lips, gums, tongue, &c. quite pallid. These symptoms continuing, anasarca follows, and death, in the great majority of cases, closes the scene. When the practice is carried to a great extent, it may be discovered by examining the stools, which will be found to consist in a great measure of the earth swallowed. Emetics are also administered for the same purpose, and the ejected matters being washed, the earth will be found to subside.*

Various means have been adopted to prevent this practice, and, among others, the affixing to the face an apparatus to prevent eating altogether except in the presence of the overseers; but all are found of no avail while the insignia of slavery are on their bodies, and the hope of freedom in another life is in their hearts. "Negroes," says Dr. Williamson, "anticipate that they will, upon death removing them from that country, be restored to their native land, and enjoy their friends' society in a future state." And upon this, the last consolation of those wretched beings, one of the means of checking the suicidal epidemic is founded. The negroes imagine that if decapitation is performed after death, the transition to their native country is prevented, and hence has been exhibited the horrid spectacle of the heads of the dead negroes placed in some conspicuous situation before their fellows.†

6. *Catalepsy.*—This disease has often been feigned, sometimes in its characteristic form, but more commonly in some of its imperfect varieties. We have nothing to add to the notice of this simulated affection in the article CATALEPSY in this work.

7. *Circulation, disorders of the.*—*Disease of the heart.*—In the French army, during

* Dancer's Jamaica Practice of Physic.

† Williamson's Med. and Miscell. Obs. on the West Indies, vol. i. p. 93.

* Loc. cit. p. 146.

the rigid operation of the conscription, almost every severe disease was simulated with the view of obtaining exemption from service, and many were adopted by the conscripts, the simulation of which must have been suggested by persons well acquainted with disease. The authors of the article on simulated diseases in the *Dictionnaire des Sciences Médicales* mention two cases which were intended to pass, and very nearly did pass, for aneurism of the heart or great vessels. In one of these a ligature was found tightly bound round the neck, and another round the top of each arm. On removing the ligatures, the purple and swollen state of the countenance disappeared, so that the man did not look like the same person, and the disordered action of the heart ceased. In the other case, a very fine ligature was so tightly bound round the neck as to be almost hid by the folds of the skin. This young man announced himself as affected with organic disease of the heart, and his terribly swollen and livid face certainly gave credibility to his statement.

It would appear from the testimony of several writers on the complaints of soldiers and sailors, that these persons are in possession of means of great power to derange the functions of the heart, and thereby to simulate and even to produce disease of that organ. Dr. Cheyne is convinced that many soldiers have the power of quickening their pulses and giving violence to the heart's action, and states that he has frequently found a soldier's pulse at the time of an expected visit, one hundred and twenty or one hundred and thirty, and the same reduced thirty or forty beats within a quarter of an hour upon his repeating his visit unexpectedly.* Seamen are said to produce such a temporary quickness of pulse by striking the elbow forcibly against a beam of wood, and this state they quaintly term *the elbow-fever*. More or less permanent derangement of the circulation is produced by the internal use of tobacco, digitalis, tartar emetic, &c.; and it is well known to all old medical officers in the army and navy that these means are familiar to the skulkers and malingerers of the two services. A much more effective means of deranging the circulation, and, indeed, many other functions, is afforded by white hellebore taken internally; and it appears from a paper of Dr. Quarrier, published by Mr. Hutchinson, that it has been extensively used in the army for this purpose. The practice was introduced into the regiment of marine artillery by a man who had formerly lived with a veterinary surgeon. This man not only produced the disorder in himself, but sold his secret and his drugs to many others. When a sudden and decisive result was sought for, as much as a drachm of the hellebore was administered; but for the more slow and progressive mode of deception, a small dose, such as from four to ten grains daily, was prescribed. The larger dose usually occasioned vomiting, purging, syncope, tremors, and great nervous

irritability, which were followed by great and inordinate action of the heart and arteries, and this was in its turn succeeded by great debility, and sometimes by a disposition to paralysis. By the smaller dose, the stomach, after a short time, became completely disordered, and much nervous irritability and consequent derangement of the circulation ensued. Various other symptoms were observed in consequence of this poison, and in some cases a fatal result was very nearly induced, and would have been so in many cases, Dr. Quarrier thinks, had not the medicine fortunately been adulterated. Many men succeeded by these means in obtaining their discharge from the service.*

8. *Contraction of the limbs producing lameness.*—This disability is often feigned by soldiers, and sailors, and very frequently by mendicants and persons who wish to escape the punishment of "hard labour." A convict who was confined on board the Retribution hulk at Woolwich, during the period of his sentence, which was seven years, kept his right knee bent so as not to touch the ground with his foot all that time; and he was on that account not sent to hard labour with the other convicts. He was commonly employed in executing light jobs, which he could do in a sitting posture. When he moved from place to place, he used to hop upon the left foot with the assistance of a stick. At the end of the seven years he was discharged, and upon going away he very coolly observed, "I will try to put down my leg, it may be of use to me now." He did so, and walked off with a firm step without his stick, which he had previously thrown away.

Mr. Hutchinson considers this imposture as that which is most common in the navy next to ulcer, and relates some curious cases. A young seaman fell from the yard-arm into the sea, and pretending, when taken up, that he had struck his loins on the ship's anchor during his fall, and had thereby broken his back, he was sent to Deal Hospital. No external evidence of injury could be discovered, but he obstinately persisted in his story, and in proof of the alleged fact he constantly kept his trunk bent at nearly right angles with the lower extremities. When a rug was placed on the floor, and he was laid on his back upon it, his legs and thighs were kept erect in the air; and when these were pressed down forcibly, he rose suddenly to a sitting posture, as if his hip-joints were ankylosed. He persevered in his deception for some time, but was soon after detected in the act of deserting from the hospital, running lustily for his liberty. A sailor on board the Druid pretended that his arm was contracted, and so immoveable was the elbow-joint that the ulna and humerus had the appearance of being ankylosed. From long want of use the muscles were wasted. The man had been for a long time excused from duty for the supposed disease. Mr. Hutchinson detected the imposture by a stratagem. Being brought up to be punished, and while

* Loc. cit. p. 165.

* Hutchinson's Pract. Observations in Surgery. Second Edition, p. 149.

eagerly engaged in conversation with the captain, his attention was withdrawn from the limb, and Mr. Hutchinson, who had hold of it, suddenly straightened it without the least effort, in the presence of the whole crew. The man was punished, and immediately returned to his duty with the perfect use of his limb.*

The following cases have come to our own knowledge. In a line of battle-ship, an excellent seaman, and a favourite with his officers, suddenly withdrew from his duty, alleging that he had been seized with a violent pain in his loins which prevented him from assuming any other than a bent position. He was long treated as a real sufferer, and every kind of application (many very severe) was used for his recovery, but in vain. After a period of many months, the surgeon was superseded by another, who soon began to entertain suspicions of the reality of the disease, and made every effort, both by severe treatment and watching, to detect him. But, by day and night, asleep or awake, the patient still retained the same position. At length, however, this accomplished dissembler, like the pretended blind-man formerly mentioned, was betrayed by the violence of his own passions. One day, being accused by a messmate of skulking, he was so incensed that he started up erect, and with all his power inflicted a severe chastisement on his accuser. He now confessed his deceit, and alleged as the cause of it the unjust and injurious conduct of one of his officers.

A seaman on board the Heron sloop pretended that he had lost, in a great measure, the use of his lower extremities, which were contracted; and he was for a long time carried by his messmates from one part of the ship to another. He was at length sent to the hospital at Barbadoes to be surveyed, and being declared an impostor, was ordered to be taken on board his own ship to be punished. On his way from the hospital, however, being made aware of what was waiting him on board, he suddenly started up in the cart, and leaped into a field of sugar-cane, and, although pursued by his attendants, succeeded in making his escape.

During the late war, a seaman was received into Gibraltar Hospital on account of a fractured leg. When this was nearly cured, he began to pretend that the ankle-joint was contracted and the foot turned inwards. This position he obstinately maintained for twelve months, in spite of every effort to restore the limb to its proper position, and in defiance of the harshest treatment. One night, however, he contrived to get intoxicated, and the surgeon having occasion to visit his ward during the night, found him lying perfectly naked on his bed, and his ankle quite straight. He was immediately returned to his ship as an impostor, was punished, and exhibited no longer any contraction of his ankle.

While transcribing this for the press, a flag-officer of the navy informed the writer that he

was once member of a court of officers who invalidated a seaman on account of a contracted knee-joint, which had resisted all kinds of treatment for a long period. On the day after he was discharged, he was seen walking upright by this officer in the town of Sheerness, and, being pursued, made his escape by a most nimble and active use of his legs.

One mode employed for detecting these pretended contractions is to place a tourniquet on the limb above the joint, by which the muscles are prevented from acting, and the joint becomes in consequence moveable. In cases of marked imposition of this kind, the naval surgeon has sometimes transferred his patients to the captain. In cases of stiff knee-joint, the practice adopted by one disciplinarian was to cause the skulker to be lashed on the back, with small cords, by the boys, until he could *run away* from them. Of course, no surgeon would give his sanction to such treatment.

9. *Deafness*.—Loss of hearing is not unfrequently feigned in the army and navy, and also by persons in civil life who wish to escape a public trial or to excite commiseration. Simulated deafness is, in general, alleged to come on rapidly, whereas the real disability takes place very gradually. Two recruits complained that they had been suddenly attacked with deafness without any previous illness. The state of the meatus was natural, and no sign of inflammation existed. The surgeon first employed the antiphlogistic regimen, and then inserted a seton in the nape of the neck, which was regularly dressed in the morning. In eight or ten days they both declared that they had regained their hearing, and requested to be allowed to return to their duty.* As in the case of blindness, the natural but involuntary language of the countenance generally evinces that the impostor continues to gain intelligence of what is going on around him through the organ of hearing. Cases of this kind are commonly detected by a little stratagem, such as making a sudden noise near the patient, or suddenly mentioning something deeply interesting to him, and watching the effect on his countenance or pulse. Foderé mentions several examples of soldiers who betrayed themselves on hearing a sudden noise. Mr. Dunlop mentions the case of a soldier in the York Military Hospital, who feigned deafness so well that firing a pistol at his ear produced no effect. He was, however, detected by the same experiment made after he had been put to sleep by opium: he then started out of bed.†

Accident also has sometimes led to a discovery of imposture, when there was no suspicion entertained respecting the alleged loss of hearing. A remarkable instance of this is recorded by Sir Walter Scott, in the introduction to *Peveril of the Peak*. A woman pretending to be both deaf and dumb, lived several years in a family, and afforded no

* *Cheyne*.

† *Beck's Jurisprudence*, p. 17.

* *Loc. cit.*

suspicion of being an impostor, until, on an occasion of great surprise, she forgot her part and suddenly expressed her feelings "in loud Scotch." In the same work a beautiful illustration of the manner of detecting the imposture, by exciting strong emotion and watching its influence on the circulation, must be familiar to every reader.

10. *Deaf-dumbness*.—This is a very common imposture among mendicants. It is also not unfrequently feigned in the military and naval service. It is of importance to know, that if a person has ever acquired the use of speech and is able to move his tongue, his dumbness cannot be real. Many singular examples of this imposture are recorded by authors; but the most remarkable is that of Victor Foy or Travanait, detailed at great length by Foderé.* This man, after deceiving a vast number of medical men in different countries, was at length detected by the Abbé Sicard. Dr. Cheyne mentions the case of a soldier who exhibited this disability for no less a period than five years, but recovered his speech upon being discharged from the service. On one occasion this man was accidentally shot in the ear by an awkward recruit, on which occasion he "expressed pain and consternation by a variety of motions and contortions, but never spoke."†

In a case of a seaman on board the *Utile*, who pretended to be deaf and dumb, the surgeon, appearing to be deceived by him, made very formal and ostentatious preparations for an operation upon his throat, and while his attention was thereby engaged, he applied a lighted candle to the man's fingers. He resisted this test, however; and having represented his case to the Admiralty, the surgeon was dismissed his ship for cruel, or at least unprofessional, treatment of his patient. Shortly afterwards, the sailor being still detained in the ship, recovered both speech and hearing. He subsequently pretended to have lost his speech only; but, finding that this faculty was not considered essential to the performance of the severest duties of a seaman, he speedily regained his tongue. This man was of a very different temper from the simpleton of whom Parr speaks. "How long have you been dumb, my good friend?" says a passenger, with the most insidious humanity. "Three weeks, Sir," replied the incautious deceiver.‡

11. *Diarrhæa and dysentery*.—Bowel complaints are sometimes feigned by soldiers and sailors and others, more particularly in countries where dysentery is prevalent, as in India. The motive for simulating this disease is commonly the escape from some particular duty. The imposture is easily detected by obliging the patient to use a night-chair; but care must be taken that he does not borrow, buy, or steal the leading symbol of dysentery, or manufacture it expressly for the occasion. Mr. Hut-

chinson informs us that he has known convicts break down in their urinary utensils a figured motion, and intimately mix it with the urine so as to induce the belief that it was in reality a diarrhæal evacuation;* and one of the writers of this article was informed by a West-Indian planter that the same deception is practised by the slaves in that country to escape labour. He knew an instance of a negro who had nearly rooted out all his teeth by tearing his gums with iron nails, in order to procure blood to make the factitious dysenteric motion more complete. These unhappy persons do not always content themselves with feigning these affections; they actually produce them by deleterious substances taken into the bowels; and Mr. Hutchinson says he has not unfrequently known them fall victims to their own imprudent attempts. It would appear that the seamen under Mr. Hutchinson's care made use of vinegar and burnt cork to effect their purposes. Mucous discharges are produced by introducing suppositories of soap or other irritating substances into the rectum, and these may be subsequently mixed with blood.†

12. *Ear, diseases of*.—A purulent and fetid discharge from the ear has been simulated or induced by soldiers with the usual object of obtaining their discharge or escaping from duty. An instance is mentioned in the *Dictionnaire des Sciences Médicales*, where honey was used to simulate a morbid discharge; and the cheat was very near proving successful. A more common practice is to introduce irritating substances, such as cantharides, into the auditory canal, and thus to excite inflammation and purulent discharge; and to render the discharge more disagreeable, rancid oil and other stinking matters have been afterwards employed. In these, as in so many other cases, careful examination will detect the imposition.

13. *Emaciation and debility*.—An appearance of unsound health is occasionally simulated for the purpose of procuring an exemption from some disagreeable service, or to obtain leave of absence, change of climate, &c. The means commonly employed are abstinence from sleep and food for a considerable time, drinking to excess of strong liquors, and frequently taking small doses of the tartrate of antimony.

Partial emaciation, or wasting of the limbs, is a much more common resource of the impostor, more particularly among mendicants. In the army or navy it is hardly possible for the individual to find time or opportunities to produce the compression by which it is effected. Sometimes, however, the circumstance, not very rare among adults, of one arm being considerably smaller than the other, is taken advantage of, and the impostor pretends that the wasting is of recent occurrence, and is accompanied with loss of muscular power or with pain. The Earl of Gloucester, afterwards Richard III., had an arm of this

* Loc. cit. p. 478.

† Loc. cit. p. 144.

‡ Parr's Medical Dictionary.

* Loc. cit.

† Cheyne, p. 170.

sort, and is related to have taken advantage of it for purposes of deception.

Every one must have seen mendicants at country fairs, exhibiting one or both arms hanging down fleshless and motionless by their sides. Almost all these have been in the first place intentionally produced by long continued bandaging, and the greater number have in reality become powerless.

Partial wasting of a limb may, however, be a real disease; we are not, therefore, to decide on such cases without due examination. In most instances the knowledge of the surgeon will enable him to discriminate between the real and the pretended disability; but we have known instances in which the discrimination was extremely difficult.

14. *Epilepsy*.—This disease is very frequently simulated in the streets. It is also not seldom feigned by soldiers and sailors for the purpose of procuring their discharge. Nevertheless, the practitioner who is intimately acquainted with the pathognomonic symptoms of epilepsy, and pays proper attention to the case, will generally be able to satisfy himself whether an alleged paroxysm of the disease be simulated or not. During a feigned paroxysm of epilepsy the contractions of the different parts of the body do not come on simultaneously; and if a patient be narrowly watched, he will be discovered to open his eyes occasionally for the purpose of observing what effect his exhibition has upon the by-standers. The simulator of epilepsy is unable to produce the red, bloated countenance and contorted face which accompany the real disease, or the immobility of the iris on the access of light. He is also apt to exhibit the appearance of foaming at the mouth either in too slight or in too great a degree. The latter result is produced by a piece of soap kept in the mouth. A marked difference between the real and feigned disease is, usually, that in the latter the patient courts publicity for his exhibitions, and makes no attempt to conceal his malady, while the real epileptic is almost always extremely desirous of hiding his infirmity. It will, likewise, be found on inquiry, that the feigned paroxysm is apt to come on very opportunely to promote the attainment of some object of desire to the patient, while the real disease shews no such intelligent consideration. It is further to be observed, that the skin is comparatively cool when the contraction of the muscles is involuntary; but if the agitation of the body be voluntary, the skin is covered with perspiration. A feigned paroxysm of epilepsy usually terminates much more abruptly than the true disease, and the convulsions are not succeeded by the comatose or soporose state that generally supervenes on the epileptic convulsion.

The most decided proof of epilepsy is, however, an insensibility to the influence of external agents; consequently, when any evidence of sense is excited by stimulants during the paroxysm, it may generally be inferred that the symptoms are counterfeited. For the

purpose of testing the degree of insensibility various means may be tried in doubtful cases. The following are some that have been used by military and naval surgeons, and often successfully.

1. A powerful general shock to the system, as by a pailful of cold water suddenly dashed upon the patient. We have more than once seen this treatment succeed in putting a period to the paroxysm; but we did not always, on this account, satisfy ourselves that the disease was feigned. So powerful a shock is not unlikely to arrest real convulsions.

2. A strong impression made upon particular senses. Mr. Hutchinson mentions a case supposed to be feigned in which the convulsions were instantly removed by blowing "some fine Scotch snuff" up the nostrils through a quill. This induced another fit—a fit of sneezing—that lasted nearly a quarter of an hour; and there was no return of the epilepsy while Mr. Hutchinson remained in the ship. The same practice was tried in real cases of epilepsy by this gentleman, but he never could produce any similar effects, although the patients were not snuff-takers. Dr. Cheyne thinks the most powerful stimulant that can be used in such cases is a few drops of alcohol introduced into the eye, and relates a case where the pretended epilepsy was instantly arrested by it. The introduction of stimulating or very nauseous remedies into the mouth, so as strongly to impress the sense of taste. Stuffing the mouth with common salt, or forcibly introducing a solution of aloes, &c. is thus often effectual in putting an end to the feigned disease.

3. The apprehension of pain or danger, excited by the proposal of an operation in the patient's hearing, or by actually placing him in a situation where he must injure himself if the convulsive movements are continued. We are informed by a naval officer that he once saw a tremendous epilepsy instantly cured by an order being given to introduce a red-hot ramrod into the patient's anus; and the dread of the actual cautery, though in a somewhat less formidable mode, has often proved a powerful remedy in similar cases. Perhaps an equally effectual plan is to *propose* to pour boiling water on the legs, and actually to pour cold water. Dr. Cheyne relates an ingenious expedient put in practice in a case of feigned epilepsy, by Mr. Young, surgeon of the 10th regiment. A large barrack-table was put upon another of the same dimensions, and the pretender placed, in the midst of his paroxysm, upon this elevated bed. The fear of a descent put an immediate termination to the epilepsy.*

In concluding these remarks, we wish to impress upon the mind of the young practitioner that he is not to be too positive in imagining that he will always be able to decide with certainty whether the ostensible epilepsy is feigned or real. In all doubtful cases, it is due to his own character as a man of honour and feeling, and due to the beneficent profes-

* Loc. cit. p. 154.

sion of which he is a member, that he take the side of mercy; and if he is ever justified in denouncing a patient as an impostor, and thereby consigning him to punishment, he is certainly never justified in being himself the instrument of the punishment. Dr. Cheyne, a man of the greatest experience, and distinguished alike for his candour and accurate observation, informs us that he is "in possession of sufficient evidence to prove that real epilepsy has often been considered feigned;" and our own experience irresistibly leads us to adopt the same conclusion.

15. *Excretion of calculi, &c.*—Soldiers sometimes feign this affection with the view of obtaining their discharge, and unwilling recruits to prevent their serving in the army. A fit of nephralgia, or passing of gravel, is even pretended, and an alleged calculus exhibited. A similar imposition is practised by females, and occasionally under such circumstances as render it very difficult to account for their conduct. A most remarkable case is recorded in the Edinburgh Medical Journal (vol. vii.) of "a young lady, of rather high rank," who feigned this disease, and was believed to have excreted, with great pain, a vast quantity of calculi, "not less than several pint measures in two or three years." The rudest chemical experiments proved the pretended calculi not to be of animal origin; they were in fact "common sand and pebble stones." No motive could be assigned for this extraordinary conduct. A similar case in a boy, ten years of age, is mentioned in the Annals of Philosophy, vol. iv. p. 76; and Dr. Thomson of Edinburgh discovered a similar imposition in a woman, by detecting micaceous particles in the alleged gravel.*

A still more common deception perhaps, and one much more extravagant, is the pretended excretion of calculi from the vagina. Many instances of this fact are mentioned by authors, and many others might be added. In a case mentioned in the Medical Comm., vol. iv. calcined bricks were pretended to be passed from the vagina, and some were extracted from it. A case was mentioned to us not long since, of a young woman from whom many fragments of coal were extracted by a surgeon. But the most remarkable instance of imposition that has come to our knowledge is that of a young woman, the daughter of a farmer near Edinburgh, who, after feigning, forming, or sustaining an immense variety of affections, in uninterrupted series, from 1817 to 1830, at length fixed upon the excretion of bone from the vagina as the great and abiding malady. Among the diseases real, feigned, or factitious, which this girl exhibited, were hepatitis, epilepsy, amaurosis, aphonia, deafness, paralysis of the arm, gravel, anasarca, hæmatemesis, irregular convulsions, gastralgia, dyspnoea, vomiting of substances resembling liver and bone, and retention of urine. Bone was first detected in the vagina in 1824, while the surgeon was introducing the

catheter, and from this period an immense quantity was either extracted or excreted; some pieces were even extracted from the bladder. She was admitted into an hospital in 1825, where she still continued to pass bones, believed for some time to be those of an extra-uterine fœtus; but a complete stop was put to the complaint by secluding the patient from all access to such materials. After her discharge the alleged excretion returned. She had an illegitimate child in 1828, and was finally married to a respectable farmer in 1830. Another young woman, in a respectable rank in life, pretended to pass vesicular bodies from the vagina, and many were extracted by surgical aid. At first the disease was considered natural, but eventually it was discovered, by Professor Thomson of Edinburgh, that the alleged hydatids were artificial vesicles prepared from the intestines of a pig. These were so constructed as to resemble a string of beads.

It is hardly necessary to say anything respecting the means of detecting such impositions; it is, however, important that the young practitioner should be made aware of their occasional existence.

16. *Fever.*—This disease is frequently feigned, and also in some degree produced artificially. Soldiers and sailors pretend to have an accession of ague during the night, and present themselves as if in the interval, to the surgeon. Sometimes they simulate the fit at a time when they can be more readily discovered. Dr. Cheyne mentions the case of a soldier who pretended to be in a *chill*, and who was seen to be shaking violently: upon throwing down the bedclothes, however, he was found not in the cold, but in a sweating stage produced by his own exertions. This exposure put an immediate termination to the paroxysm.* Such persons, Foderé says, often imitate admirably the chattering of the teeth of the cold fit. They likewise use means to produce a greater semblance of fever. Great heat and perspiration, and a quick pulse, are produced by strong exercise immediately before the hour of the visit. In the section on disordered circulation, we have noticed various means adopted for the purpose of disordering the action of the heart and arteries, most of which are equally applicable to the production of the disease now under consideration. The skin is sometimes scrubbed with a hard brush to produce redness; and the tongue is very frequently coloured artificially white, brown, or dark, with chalk, pipe-clay, tobacco, brick-dust, and brown soap, &c. according to the convenience or knowledge of the impostor. The sanguinary pirate Loto, who was lately executed at Gibraltar, very nearly succeeded in deceiving his medical attendants by simulating fever, colouring his tongue brown, &c. In all these cases close observation will almost always detect the imposture; and most certainly a few days' confinement will do so. It is only an ephemeral fever that can be feigned with any prospect of success.

17. *Fracture.*—We have seen several sol-

* Beck's Jurisprudence, by Dunlop, p. 7.

* Op. cit. p. 175.

diers who simulated lameness, and alleged that a thigh bone had been fractured, by which means the limb had become shortened. This imposture is easily detected by placing the man upon his back and examining both the thighs: the muscles of the limb falsely alleged to be shortened will be found hard and in full action, while the muscles of the other limb are inactive and soft. We happened to know one instance of a soldier who obtained his discharge by alleging that he had a plate of metal in his skull, which he said had been introduced there in consequence of the bone having been fractured; and we are also aware of an instance where a medical officer was found fault with for having approved of recruits "with plates introduced into their heads." The simulators of this disability must have met with very credulous auditors, for it is to be presumed they did not examine the heads said to be thus mended.

18. *Hæmatemesis*.—This affection is readily simulated, and frequently has been so by soldiers, sailors, slaves, and other persons. It is effected by procuring blood, and after swallowing it, producing artificial vomiting, whereby it is disgorged. The blood is generally that of some animal; but slaves in the West Indies have been known to swallow their own blood to effect their object. A remarkable case is mentioned by Sauvages, of a girl who feigned hæmatemesis to escape from a convent, and who brought up in the presence of the physician several pounds of blood on several successive days. It was at last discovered that she secretly drank bullock's blood before the visit.* This imposition will in general be discovered, at least in situations where the medical attendant may reasonably expect to meet with feigned diseases, by narrowly examining the symptoms—when a discrepancy and want of harmony will be found among them which nature never presents. When any suspicion is excited, the detection may be made at once by watching the patient, and cutting off the possibility of his obtaining the materials necessary to the simulation.

19. *Hæmaturia*.—This disease has been sometimes simulated by taking substances into the stomach which have the quality of reddening the urine, such as beet-root, the fruit of the prickly pear, madder, &c.; it has, however, been much more frequently attempted to impose by mixing foreign substances with the urine, particularly blood, after it was excreted. The authors of the article *Feigned Diseases* in the *Dictionnaire des Sciences Médicales* inform us that blood has even been injected into the bladder with this view. A little attention suffices to discover factitious hæmaturia, however produced.

20. *Hæmoptysis*.—This is a disease very commonly feigned by soldiers and sailors, and also by mendicants. The cough is easily assumed, and the sanguineous expectoration is produced by pricking or cutting the gums, throat, or some part of the mouth, or by cut-

ting the fingers or arm and sucking the blood, or by procuring the blood of animals, or by artificially tinging the sputa of a red colour by some foreign substance. Sylvaticus mentions the Armenian bole as being used for this purpose;† Dr. Beck, brick-dust; and Mr. Hutchinson vermilion paint. Dr. Cheyne justly observes that the absence of the symptoms which generally attend real hæmoptysis, such as cough, dyspnœa, fever, &c. will naturally excite suspicion, and the appearance of the sputa will confirm this in such cases. The factitious will be very unlike the real sputa of hæmoptysis. The use of the stethoscope will greatly aid in the diagnosis in doubtful cases. It ought to be a rule in the army, that simple spitting of blood, unaccompanied by signs of organic disease of the lungs, is not a sufficient cause for the discharge of a soldier.

21. *Hæmorrhoids*.—The discharge of blood from the anus is easily feigned or imitated. It appears also that hæmorrhoidal tumours have been very artfully constructed by means of small bladders, inflated and tinged with blood, and attached to a substance introduced into the rectum.‡

22. *Hepatitis*.—This affection is often simulated by soldiers who have been some time in India, when they wish to be discharged. They are commonly well acquainted with the symptoms of the disease, and frequently tell a tolerably consistent story. The countenance and general appearance of an impostor of this kind are, however, often at great variance with his oral testimony. In doubtful cases of alleged organic disease of the chest or abdomen, the person to be examined should be undressed, as he is then unable to conceal whatever evidence of health may be supplied by a plump frame and muscular limbs. An opportunity is also thus afforded of properly exploring the cavity in which the disease is alleged to have its site.

It is not an uncommon practice with officers in the navy on foreign stations, who are desirous of returning to England, to feign some disease in order to be invalided to a more temperate climate. In the West Indies in particular, this practice was formerly of frequent occurrence; and it is a curious fact that the disease most frequently assumed, and successfully, was that now under consideration, and which is by no means very common among sailors in that country. The causes of this preference in favour of hepatitis are, no doubt, the supposed facility of imposing the belief of its existence on a superficial observer, and the generally received opinion of the tendency of all tropical climates to generate it.

The fact just stated might lead to some curious statistical mistakes. Suppose, for instance, information were sought respecting the relative prevalence of different diseases in different climates among persons in the navy. If the official records of the medical department

* *Institutio medica de iis qui morbum simulant deprehendendis*.—*Madrid*. 1594.

† *Percy and Laurent*, op. cit.

* *Nosol. Method. t. ii. p. 299*.

were inspected for this purpose, it would be found that a large proportion of the invalids from the West Indies were affected with hepatitis; and it is probable that the proportion might be greater than among the invalids from the East Indies. Now there cannot be a doubt that liver-disease is, in truth, *much* more prevalent in the latter climate than in the former. Owing to particular circumstances those invalidated for complaints of this kind from the West Indies are chiefly officers; and the much greater proportion of this class than of common seamen, in the invalid lists, might be considered as indicating some peculiar causes of hepatitis among officers in that country.

Dr. Cheyne has some very sensible remarks on the feigned hepatitis of soldiers. He says that "when men who have not been in warm climates obstinately complain of pain in the right hypochondrium, and when we cannot discover any enlargement or fulness of the liver, when the pulse and breathing are undisturbed, the secretions and excretions natural, and when the alleged pain resists topical bleeding and blistering, and mercurial purgatives, the sooner we send them to duty the better." Persons in this class often eventually succeed in their object of dismissal from the service, chiefly from the mistakes of the surgeon. "Such subjects," says Dr. Cheyne, "have often come under my care with their flesh and strength reduced by repeated courses of mercury, their gums absorbed, and teeth shaking in their sockets, whose livers were sound (probably they never were otherwise), but whose broken health required that they should be invalidated without delay."*

23. *Hernia and Hydrocele*.—Both these diseases have been frequently simulated. The means most frequently used to effect the object, is inflating the cellular substance of the scrotum. But more artful and more severe means have been adopted. Cases are related in the Act. Nat. Cur. of inflated bladders being applied to the scrotum to impose on the ignorant; and it is to the great discredit of the medical profession that some of its members have aided in the production of deceptions of a more scientific description. In the year 1828, two medical men were tried in France for having, respectively, produced in four conscripts swellings of the testicles. It was sworn by one of the conscripts that the operator injected into a wound made by him in the scrotum, a red-coloured liquid which gave him excessive pain. The operation was followed by violent inflammation of the testis. The other operator applied caustic to the scrotum with the same result. This last individual, a surgeon of the name of Desplats, was sentenced to the pillory and five years' imprisonment. The practice of inflating the scrotum is much more common, because more easy. Sir Astley Cooper mentions the case of a man at Norwich who imposed on the surgeon by this means, and thus escaped serving in the army: and we have more than once seen the same plan adopted,

but without success, by impressed seamen. A small blow-pipe, or the stalk of a tobacco-pipe, is the instrument commonly used. It is hardly necessary to say that no surgeon *ought* to be deceived by a case of this kind.

Some men have the power of retaining the testes in the groin by the voluntary action of the cremaster muscles; and the swellings resulting from such a position of the parts have been mistaken for hernia.*

24. *Hydrocephalus*.—Chronic hydrocephalus has been simulated at least in one case which we shall quote from Sauvages, who terms the case, after Mangetus, *physocephalus artificialis*. In the year 1593, a mendicant exhibited his child for gain as a monster, on account of the immense size of his head. This preternatural appearance was produced by the daily insufflation of air under the scalp, by means of a pipe introduced into a small perforation on the vertex. By this operation, repeated for several months, the scalp at length became extended to an enormous degree. Being detected, this wicked father was condemned to death.†

25. *Hydrophobia*.—One would hardly expect that this disease should ever have been feigned. MM. Percy and Laurent, however, mention a case of the kind in a conscript, which, although terrifying the examiners at first, was eventually cured by the threat of suffocation between two beds.

26. *Incontinence of fæces*.—We have known this disease feigned. A boy on board the *Desirée* frigate pretended that he could not retain his fæces, and was frequently found voiding them on all occasions and in all places. Being deemed an impostor, he was severely punished, and at last confessed that he had been advised to do so by his aunt, that he might be discharged the service: this result he was very near obtaining. The following remark of Dr. Cheyne, relative to this pretended malady, is very judicious. "When a patient alleges that he cannot retain the contents of the bowels, the sphincter ani ought to be examined, and if it contracts upon the finger, opium, with solid food, must be prescribed, and a watch set over the individual: if he passes solid fæces in bed, he will be a fit subject for a court martial."

27. *Incontinence of urine*.—It is somewhat singular that a disease so very rare as this is among persons not advanced in life, should be one very commonly feigned, more particularly by soldiers. This arises, probably, from the circumstance that the infirmity is easily simulated, and is one particularly inconsistent with the habits of neatness and cleanliness required in a modern soldier. This disease was extremely common among the French conscripts during Napoleon's wars. Its very frequency of occurrence among soldiers is in itself a strong presumption of imposition; and if it makes its appearance at all in an epidemic form, we may be almost certain that it is feigned. MM. Percy and Laurent say they have had no fewer than fifteen pretended cases of this

* Loc. cit. p. 172.

* Hutchinson, loc. cit.

† Nosol. Method. t. ii. p. 497.

kind at one time in a recruiting dépôt; and Foderé witnessed its occurrence, almost in an epidemic form, in consequence of two soldiers having obtained their discharge on this account. Dr. Cheyne notices a somewhat similar circumstance in an English regiment, in consequence of the facilities the soldiers found in imposing upon a practitioner unacquainted with military practice.

Independently of evidence derived from collateral circumstances, there are many means of detecting simulated incontinence. When the disease is real, the clothes of the individual usually exhale a strong ammoniacal odour, which is not often the case when the disorder is feigned. The simulator commonly chooses the time and place which appear to him the best for wetting his clothes: if he sleeps with another person, he is more apt to wet his bed than when he sleeps alone; and if he is furnished with clean straw to lie upon, he does not commonly wet it before the morning. In real incontinence, more especially if it has existed some time, the glans penis is stated by MM. Percy and Laurent to be pale and shrivelled, from being kept constantly wet with the urine which comes away *guttatim*; and Foderé says if a ligature be passed round the penis in such cases, the urethra will soon be found distended above it. It is evident, however, that this test cannot be depended upon. In the Austrian army, a man who alleges that he has incontinence of urine is furnished with a urinal and obliged to do his duty. In the French army it was customary to compress the penis between two pieces of wood; and Foderé informs us that he succeeded in putting a stop to a fictitious epidemic of this kind by applying a sealed ligature to the penis, which was only allowed to be undone by a person appointed for the purpose. MM. Percy and Laurent prescribed with perfect success in a case of this kind, twenty lashes on the loins, with the avowed object of strengthening the debilitated part; and the surgeon of a regiment mentioned by Dr. Cheyne, speedily put an end to a pretended epidemic of the same kind by prescribing a cold bath twice a day in Lough Neagh. Such means as these, with blisters to the perineum, and other appropriate but disagreeable remedies, will almost always put an end to this alleged disability, even when we have not been able to demonstrate to the simulator himself that we have detected him. When this is once effected, there is never any difficulty in curing any feigned disease. The most effectual mode of detecting simulated incontinence is that prescribed by Mr. Comyns, an army surgeon, and afterwards by Dr. Hennen and Mr. Hutchinson, viz. to administer a strong opiate at bed-time, and to watch the length of time the urine is retained during sleep; or to introduce the catheter unexpectedly, to ascertain the quantity of urine found in the bladder. In real incontinence, the bladder will not retain its contents after a certain time during sleep, or under any other circumstances. The following ingenious method was successfully used by an army surgeon to detect and

cure a fictitious infirmity of this kind. The surgeon having ascertained from the patient how long he could retain his urine, (of course a very short period,) caused him to undress and stand before him with the abdomen exposed. Upon observing the abdominal muscles called into action to aid in the expulsion of the urine, he suddenly and forcibly thrust his fingers against the belly so as to prevent the voluntary muscular effort. This he repeated as often as he saw the action renewed, until the alleged period of expulsion was long passed. He then dismissed the patient with the remark that he had retained his urine long enough to enable him to do his duty.

The opposite state of *retention of urine* has been sometimes feigned, more particularly by female convicts. A strict watch will always detect such an imposition.

28. *Jaundice*.—The yellow colour of the skin in this disease has been simulated by painting it with an infusion of curcuma or tincture of rhubarb, &c.; and it is said clay-coloured stools have been imitated to perfection by taking daily a small quantity of muriatic acid. What it is impossible to feign or to form, however, is the yellow colour of the conjunctiva, and the want of this will always detect the imposition. It will rarely happen that a simulator will be so ingenious as to produce, at the same time, the yellow skin, the pale stools, and the dark-coloured urine. An ingenious device for altering, at least, if not rendering yellow, the conjunctiva, was that of a French conscript, who always put snuff in his eyes before the surgeon's visit.*

29. *Madness*.—Mental derangement, in some of its forms of idiocy, melancholia, or mania, has been in all ages assumed as a means of attaining certain objects of desire. The names of many persons famous in ancient and modern times are associated with this imposture. Madness is most commonly feigned in civil life by prisoners to escape punishment. In the army and navy, and among slaves, it is feigned with the same object, as well as to escape from disagreeable labour; but in the army and navy it is still more commonly feigned with the view of obtaining a discharge from the service. In the latter department of the public service, during the late war, in which so many hearts were broken by the hope too long deferred of returning home, every surgeon of experience met with instances of simulated insanity; and it was equally common among the numerous prisoners of war detained for so many years in this country. All the forms of disordered intellect were feigned; but the most common was that of furious madness, assumed with the view of effecting a temporary purpose, such as the evasion of punishment, the removal to an hospital, &c. When the design was to obtain a discharge from the service, melancholia or idiocy was the form adopted. In several instances the simulators succeeded in gaining their ends; in many others they were detected; and we fear that in not a few instances real

* Dict. des Sciences Méd. loc. cit.

insanity was mistaken for feigned, and the patients were treated as impostors. This fact ought to lead the medical officers in the public service to study with great care the indications of insanity, and ought moreover to induce them, wherever there is a shadow of doubt, to lean to the side of mercy. It is infinitely better that they should be deceived, than that a poor wretch, already suffering under the most grievous of natural calamities, should undergo additional misery from their ignorance.

The discrimination of the fictitious from the real disease is not always so easy as those who have never witnessed both are apt to imagine. It is true that when we consider the very peculiar and complex phenomena which characterize true madness, and reflect on the general ignorance of those who attempt to imitate them, we have no right to expect such a finished picture as could impose on persons well acquainted with the real disease. And yet when, on the other hand, we consider how imperfectly the operations of the intellect, both in a state of health and disease, are known to medical men in general, and how few opportunities the medical officers in the public service have of observing the phenomena of insanity, and reflect how natural it is for the feelings of honourable men to take the part of ostensible distress, it need not surprise us that the pictures drawn even by such rude hands have imposed on educated minds. But it is less because fictitious madness has been treated as real, than because real madness has been treated as fictitious, that we are so anxious to direct the attention of junior medical officers in the army and navy to the study of the characteristic features of the disease. These can be only thoroughly studied in the receptacles for the insane, but much knowledge of importance may be derived from books. Referring the reader to these sources, we must content ourselves in this place with a few general observations.

The form of madness that can be assumed with most facility is that of furious mania; and yet the cases of this which we have witnessed have been all lamentably defective as imitations of nature. The actors always overdid their part. They sought to personify the notion of madness usually entertained by the vulgar, viz. the total abolition of the rational faculty, instead of its partial perversion. It is still more difficult to simulate the quiet half-rational insanity of the melancholic or monomaniac; as nothing but careful observation of persons so affected can qualify an individual for such a difficult task. This statement might be illustrated in a curious and interesting manner by a reference to the writings of poets and novelists. Such persons are obviously much better qualified to paint the disease now under consideration, than the ignorant soldier or sailor; and yet it would not be difficult to point out, in the numerous delineations of insanity presented by authors, such glaring deviations from nature as could not fail to strike any one versed in the history of the disease. Shakspeare, Goëthe, and a few others

perhaps, might stand the application of the severest test; but the common class of writers who have attempted such delineations have failed completely.

Idiocy has been more successfully imitated; and, perhaps, this may be accounted for by the opportunities which most men have enjoyed of studying the character in the instance of the poor idiot, still to be met with at large in almost every village. Conscripts have pretended that they were incapable of being taught the commonest duties of a soldier; and we knew an instance of a young *player*, drafted into the army, who acted the part of an idiot so effectually that he soon obtained his discharge. Almost immediately after this he enlisted into another regiment, and then deserted.

Independently of the mental phenomena of insanity, there are many physical conditions of the system often present in this disease, which it is hardly possible to feign, such as the expression of the countenance, the state of the eye, of the tongue, &c. One very common symptom, and one indeed invariably present in the earlier stages of furious mania, and in most of the forms of monomania, is sleeplessness; and this it is hardly possible for any man to feign. A real madman will be many days, even weeks, without sleep. This circumstance alone, if properly taken advantage of, will suffice to detect most impostors; and in order to derive from it all the advantages which it is capable of yielding, a strict and uninterrupted watch should be kept on all patients who are suspected of imposition. In the case of a seaman who enacted under our own eye the part of a furious maniac, in hopes of escaping punishment, sound sleep overpowered him on the second night of his attempt. Abstinence from food is another circumstance respecting which there will often be observed a marked discrepancy between the real and the pretended madman.

A strict watch will also generally detect in the simulated disease, great variations of violence, incoherence, or other symptoms, having reference to the visits of the medical officer, the being overlooked, &c. A pretended maniac will often be tranquil when he believes himself alone, or only in the presence of those of whose opinion he is regardless. A bold and clever dissembler will, however, not leave himself thus exposed to detection. We are informed by a gentleman, once in charge of French prisoners of war in this country, that he has known men (afterwards detected and admitted on their own confession to be impostors) carry their simulation to so exquisite a height as to eat their own excrements, even when shut up in their cells, suspecting they *might* be overlooked.

Real madness is seldom sudden in its attack; feigned madness very generally is so. The real disease usually exhibits itself at first in slight and almost imperceptible deviations from the habitual modes of thinking and acting, not reaching its height in many cases until after a progressive increase of months, or even years; although, perhaps, the change at last

from a comparatively slight degree of hallucination to extreme violence has been sudden. The feigned disease, on the contrary, is rarely preceded by such indications, but bursts out in full violence at once upon the application of some exciting cause. And yet this rule is not without exception in both cases. We have seen instances of sudden and furious insanity in civil life without any premonitory sign.

The circumstances under which the alleged insanity has supervened, the man's previous character, the probability or improbability of the disease being assumed, and many other obvious considerations, will all materially assist the diagnosis. For instance, if we find a man not previously liable to be so affected, nor hereditarily disposed to insanity, suddenly exhibit the appearance of this disease under an impending trial or punishment, or other threatened evil, which might be averted by such a state, there is certainly a presumption in favour of the disability being feigned. It is however to be borne in mind, that the very same apprehension of exposure, disgrace, or punishment, which affords motives for simulating insanity with the view of escaping them, may give rise to the real disease. Instances of this kind have been mentioned to us as occurring in the public service, and it would be easy to supply others from history and the records of jurisprudence. For this reason, and because we believe with Dr. Cheyne on other grounds, that "we are in more danger of supposing insanity simulated when it is real than of considering that disease to be real when it is only pretended," we must strongly protest against the decision in any case, that the disease is feigned, solely because there appears a strong reason for its being so. Taken in conjunction with the actual phenomena and other collateral circumstances, the consideration of the probable motives will, however, no doubt, in many cases greatly aid the diagnosis.

The existence or non-existence of causes known to predispose to insanity will be considered in every particular case, and they will have their due weight. Of this kind are previous attacks of the same malady under circumstances where there existed no apparent motive for deceit; the existence in the patient's family of a similar disease; eccentric habits, or what may be termed the maniacal temperament; a decidedly strumous habit; the application of strong exciting causes of a moral nature; physical disorders, especially such as are known to affect the brain, as prolonged intoxication, previous injury of the head, the repression of cutaneous eruptions, &c. &c.

It is well remarked by Dr. Cheyne, that in real insanity there is often the greatest insensibility to decency, propriety, and comfort, evidenced by the grossest language in persons previously of very pure minds, by exposure of the person, spitting heedlessly in all directions, passing the excrements in bed, or plastering them on the walls of the cell, &c. circumstances not likely to exist, at least in the same degree, in simulated cases. Yet this only affords us collateral aid in the diagnosis.

Foderé has related the case of a young woman, undoubtedly a pretender, who committed every kind of indecency in her cell; and the miserable trait formerly noticed of a prisoner of war devouring his own excrements, is a convincing proof that nothing is too disgusting to appal a determined will.

In addition to the means of diagnosis supplied by the actual phenomena of the malady, by its previous history, and by other collateral circumstances, we have, in suspicious cases, a very important means in the institution of plans calculated to outwit an impostor or to overcome his obstinacy. Many harsh measures have been had recourse to in the army and navy with this view, which are altogether unjustifiable, except in cases of the clearest imposture. In no case, however suspicious, is the medical practitioner authorized to go beyond the employment of means of a strictly professional kind. He may, indeed, use all the artillery of annoyance supplied by medicine, and he may even *threaten* extra-professional infliction; but he must never go beyond this line. When convinced of the imposition in the case of a soldier or sailor, it is the duty of the medical officer to state his opinion to his military superiors; the *punishment* of such a crime is altogether foreign to his station and profession. Still, both the threat and the actual infliction of punishment have often put an end to simulated madness. In a case which occurred in the navy, a sailor who evinced a great desire to throw himself overboard, but was for a time prevented, at length succeeded in doing so; immediately on reaching the water, however, he began to swim vigorously, and called loudly for a boat. Upon being taken on board his madness had disappeared, and it did not return. The practice of former times would sanction a conjecture that this might have been a case of real insanity cured. In the case of the girl mentioned by Foderé, his informing the keeper in her presence that on the morrow a hot iron would be applied between the shoulders if she was not better, was immediately followed by great amendment. Actual punishment has often been advised, and even employed, where there existed merely suspicion of imposture; and, although condemning the practice, we must admit that it has frequently been successful in detecting deceit. Zacchias relates a case in which a physician recommended corporal punishment, on the principle that, if the madness were simulated, the cheat would not stand the test, and if it were real, the flagellation would do good as a derivative; and the event proved the accuracy of the first opinion.* The same means, however, and others equally severe, have often been employed without such a fortunate result, in equally suspicious cases. Examples of this sort, we have reason to know, were by no means extremely rare in the army and navy during the late war. A melancholy instance of real insanity treated as feigned is related in Mr. Marshall's Hints to young medi-

* Foderé, p. 460.

cal Officers (p. 140 ;) and we could enumerate others of a similar kind which occurred in the navy.

Some cases have come to our knowledge where deception was believed and punishment inflicted, yet, in which evidence of the reality of the disease was most conspicuous. In one of these, which occurred on board H. M. ship —, two circumstances ought at once to have opened the eyes of the surgeon, viz. the periodical recurrence of the affection, and the total sleeplessness that prevailed during the paroxysm. They were also, we suspect, much less uncommon in civil life formerly, when the execution of the laws against vagrants was more summary than at present.

In this, as in all other feigned diseases, impressing the impostor with the hopelessness of his attempt to succeed in gaining his object, will be found the most effectual means of putting an end to the simulation. A few words intentionally dropt in the patient's hearing, but as if incidentally, expressive of the expectation entertained by the medical attendant that the case would be cured, and of intended perseverance in the treatment then pursued, have often proved prophetic. We have known instances of a stop being almost immediately put to simulated madness by sending the soldier to the dépôt for the insane.

It is fortunate that the very treatment most suitable to the recovery of persons really deranged is that which is most intolerable to the impostor. None but the most determined characters will be long able to resist the horrors of solitary confinement, bread and water, and the constant pain of blisters and other counter-irritants. Seclusion is particularly necessary in all such cases, as nothing tends so much to keep alive the hopes and the courage of the impostor as the consciousness that his raving is heard by his fellows, and the belief that an impression favourable to his views may be made on the minds of his officers, by the continued exhibition of his miserable state.

30. *Malformation*.—Deformity, such as curvature of the spine, elevation of one shoulder, shortness or distortion of a limb, inversion of the feet, &c. are occasionally simulated by soldiers, and sometimes with so much success that they obtain their discharge on that account. It may be said that a man who feigned deformity would readily be exposed by a medical practitioner who is intimately acquainted with the healthy configuration of the human body. This opinion seems to be well founded, yet cases occasionally occur from which it would appear that a simulator of deformity is not easily detected. We are acquainted with more than one instance where a board of medical officers have recommended recruits to be discharged from the army on account of alleged great deformity, but who were, in fact, remarkably handsome well-made men, and afterwards enlisted and were approved for service.

31. *Needles in the body*.—Among the various factitious disabilities, induced or voluntarily submitted to by patients, the singular one

of the introduction of needles into some part of the body deserves particular notice. The two following cases will point out the character of this affection.

In July 1818, a young woman was admitted into Richmond Hospital, Dublin, on account of a painful swelling of the left hand and arm, somewhat resembling that which occurs in phlegmasia dolens. The inflammation continued to increase, diarrhoea supervened, and her general health became greatly impaired from the constant pain and irritation of the disease. Amputation was performed close to the shoulder-joint on the 21st of September. On examining the arm, eight or nine needles were found in the palm of the hand and forearm. The cause of the inflammation was now evident. This woman eventually confessed that she herself introduced the needles into her hand and arm, and she would assign no other reason for so doing but that she was tempted by the devil. An unwillingness to labour so as to procure a livelihood seems to have been the efficient cause of her exciting inflammation for the purpose of being admitted into an hospital. For several years after her arm was amputated she was employed in Richmond Hospital as a servant.*

The case of Rachel Hertz is perhaps still more remarkable. At about the age of fourteen, on the 16th of August, 1807, this woman became a patient of Professor Herholdt of Copenhagen. From this date until February 1819, she suffered under a variety of anomalous complaints; and especially an affection resembling hysteria, or epilepsy, or both. About this time a tumour appeared near the umbilicus; and being opened, a needle was extracted from it. From the 12th of February, 1819, till the 10th of August, 1820, a period of eighteen months, this woman had a number of abscesses formed in different parts of the body, from which two hundred and ninety-five needles were at different times extracted. Her superior and inferior extremities became paralytic, and continued so for a long period; but she eventually recovered. Swellings, or abscesses, containing needles, continued to appear from time to time; so that from the 28th of May to the 10th of July, 1822, one hundred were extracted, altogether amounting to three hundred and ninety-five. It was supposed by Professor Herholdt and Dr. Otto that she had swallowed the needles during her paroxysms of hysteria or epilepsy; but the truth was ascertained in a very simple manner. A young girl was observed in the act of introducing needles under the skin of her arm; and being asked who had taught her that trick, her answer was, that she had seen Rachael Hertz introduce needles under her skin.

32. *Ophthalmia*.—Factitious ophthalmia is, we believe, rare in civil life. It was very frequent among the French conscripts during the late war; no fewer than twelve per cent. of the inefficient conscripts belonging to the depart-

* Phrenological Journal, vol. ii.

ment of the Seine, during a period of ten years, were rejected on account of "impaired vision—diseases of the eyes." During the first ten or fifteen years of the present century, inflammation of the eyes prevailed to a great extent in some regiments of the British army, and there is much reason for supposing that factitious ophthalmia was then frequent. The following is one of the most extensive instances of factitious ophthalmia that has come to our knowledge. In the year 1809, three hundred of the men of two regiments which were on duty at Chelmsford, became affected with ophthalmia. The healthy men of the corps were removed to another station, and the sick remained in hospital, but under military command. Information having reached their commanding officer that one of the nurses of the hospital was in the habit of going to a druggist's shop for the purpose of purchasing medicines, suspicions were excited; and in conjunction with the medical officer in charge of the hospital, he made a successful attempt to discover whether the men had any drugs in their possession which might be employed to excite inflammation of the eyes. Accommodation having been provided for about twenty-four men, the number contained in one ward, at midnight the officer made his appearance in the hospital; the men were roused from their beds and forthwith marched in a state of nudity to the new ward. The old ward was secured for the night; and next day when the beds were examined, a number of small parcels of corrosive sublimate were found concealed. Means were taken to prevent a supply of this article, and in a very short time two hundred and fifty of the men had recovered, and were then marched to their respective corps.

The means that have been known to be used by soldiers to produce ophthalmia, besides the above, are powdered alum, snuff, salt, lime, tobacco-juice, &c.; also, mechanical irritation of the eye by hard bodies, extraction of the eye-lashes, &c. Presumptive evidence is, in general, all that can be obtained respecting the production of this disease; but many circumstances are calculated to excite suspicion in the situations where it is likely to exist. Among soldiers it has been found that the *right eye* has suffered chiefly, because this is the important organ to a modern man of war. The extreme rapidity of the progress of the inflammation in the factitious ophthalmia is often a guide to the real nature of the disease: it sometimes reaches its acmé in a few hours, a circumstance never observed in the natural disease. It is much more difficult to detect the disease in a chronic state. It is not improbable that the destruction of the eye among soldiers has been promoted by the large pension which government has allowed to those who are discharged on account of impaired vision. Formerly every man who became blind of one eye was discharged and received a pension for life of annuence per day. This usage is, however, amended in the new pensioning warrant; for it is there ordered that "no soldier

shall be discharged for the loss of one eye, whether it be the *right* or *left*." This regulation, if put effectually in execution, will in all probability lead to a great diminution of the prevalence of ophthalmia in the army.

When the disease is once detected, the cure of it is obvious; but much difficulty is often experienced in putting an end to it where it is merely suspected. When perfect seclusion cannot be obtained, as in the navy, a strait waistcoat has been used to prevent the patient tampering with his eyes.*

33. *Pain*.—There is perhaps no morbid affection more frequently feigned than this; among the disabilities assumed for the purpose of obtaining a mere temporary object, there is certainly no one so often met with. It is the usual resource of the worthless and mean-spirited among soldiers, sailors, and slaves, to obtain a few days' respite from labour. The vulgar see little in real disease but pain, or they at least look upon pain as the common symbol of disease, which they regard as something superadded to and existing separately in the body. They constantly describe any chronic ailment as an entity; "it goes here, it flies there, it works in the bowels," &c. These flying or migratory pains are very common among soldiers and sailors, and are known by the cant name of "*the all-overs*;" they are readily detected by a little art. If the surgeon listens attentively to the narrative, and begins to catechise his patient with apparent simplicity and good faith, he may bring him to admit the existence of any symptom however absurd, and thus to betray himself.

By the more cunning and more resolute the existence of severe pain, fixed in some particular spot, is feigned with more success, and often indeed with astonishing constancy. Many instances are recorded, and several have come to our own knowledge, where individuals have supported their assumed character for a long period, under every privation and much real suffering. A remarkable case of alleged pain in the mamma, in a female mendicant, is related by Lentin,† which could only be admitted as feigned on the clearest evidence. This woman went so far as to solicit, and at length to obtain, the amputation of first one mamma and then the other; and, not content with this, she afterwards wished one of her hands to be amputated on account of a similar pain, of which she alleged it to be the site. This woman was proved to be an impostor in respect of part at least of her alleged maladies; and she was considered by Dr. Lentin and other competent judges as equally so in regard to the pain. The following cases related by MM. Percy, Laurent, and Foderé, are remarkable examples of the same kind.

A young man having been deceived by a recruiting officer, who promised that he should be made an ensign on his joining the regiment,

* Hutchinson, loc. cit.

† Beytraege zur ausubenden Arznei wissenschaft, Leipz. 1797.

formed the resolution of attempting to obtain his discharge by simulating disease. He complained of having a deep-seated pain in the left knee-joint, on account of which a great variety of remedies were applied, including blisters and moxa. The leg became by degrees extenuated, and he was sent to the baths. At last, after being four years under medical treatment, he obtained his discharge. Upon leaving the hospital, some of his comrades accompanied him a little way on the road, whom he treated with wine; and before they parted he took off the wooden leg he had worn for three years, and threw it into the fire, saying, at the same time, "they deceived me, and I in my turn have deceived them."

A soldier came under Foderé's care in the hospital of Martigues, complaining of a violent pain in the left leg, which he represented as arising from his having slept on the damp ground. During a period of eight months the most severe and painful external applications were made, and medicines given internally without effect. He still continued in bed, being unable, as he said, to stand. The leg having become wasted from the repeated use of blisters and issues, and apparently shorter than the other, and he being moreover pallid and emaciated in consequence of the severe regimen to which he had been subjected, Foderé at length obtained his discharge. While waiting for this, however, he was one day detected marching without any assistance, and, being taken up, at last acknowledged the imposition.*

Pains are also frequently feigned in the internal cavities of the body; and probably these may often be more easily detected than such as are alleged to have their site in the external parts, inasmuch as pains of a simply nervous character are perhaps of less frequent occurrence in the former situation, and pain depending on other causes will be accompanied by other appropriate symptoms. Still it must be admitted that detection in cases of this kind is more likely to be obtained through means of collateral evidence than by the absence of positive and sensible indications of disease. Every experienced practitioner has witnessed cases of most severe pain in almost every part of the body in persons who could not be suspected to feign; and the whole history of that great and increasing class of diseases termed *Neuralgie* is but a melancholy testimony in favour of the possibility of real pain being unmarked by any certain external signs. Too often, we fear, has the absence of symptoms in such diseases been the cause of great additional suffering to the victims of neuralgia in the public service; and we cannot more emphatically impress on the mind of the young medical officers in the army and navy the necessity of caution in such circumstances than by relating the following cases.

A young soldier, under the care of Foderé, complained of violent pains in various parts of

his body, now in one limb, now in another, in the chest, head, &c., unaccompanied by any other symptom. Considering these pains as fictitious, Foderé refused to give the man his discharge; but he nevertheless died in the hospital without any new symptom. "After his death," says Foderé, "I anxiously explored, by means of the scalpel, all the old seats of the pains, but could discover nothing, in the membranes, the muscles, the nerves, or the viscera; and I was forced to believe that life had been destroyed by the long continuance of the pains. Since then," the author adds, "I have often preferred rather to be too lenient than to run the hazard of being again unjust."*

A seaman on board one of His Majesty's ships applied to the surgeon, complaining piteously of a pain in his shoulder preventing the motions of the arm. He could assign no cause for it, alleging that it came of itself and gradually increased to its present violence. No external mark could be discovered, and it being suspected to have arisen from some slight strain, it was ordered that the part should be rubbed with a common liniment. This was continued for a fortnight without relief; blisters were then applied and kept up for another fortnight. There still appearing no external sign of disease, the surgeon, suspecting imposition, ordered the man to move his arm before him. The poor fellow hesitated, and, begging to be spared, was allowed to rest for a few days, when the arm was forcibly moved by another person. It was in vain that the man entreated them to spare him; the surgeon, confident in his fancied knowledge, and resolved to punish what his nosology told him was imposture, ordered a rope and a weight of eighteen pounds to be brought; he was commanded to swing the one, or to bear from the other the punishment which his alleged *crime* deserved. He implored, he hesitated; when the rope, laid on with no slight hand on his shoulders, made him seize the weight; but scarcely had he freed it from the deck when he was forced by pain to throw it down. This scene was exhibited for some time, and sullen resentment at length getting the better of patience, gave additional force to the surgeon's opinion. The man was about to be returned to his duty, and to be punished as an impostor, when a fatal evidence appeared to testify against the sentence of his cruel and ignorant judges: a slight swelling showed itself on the part with signs of fluctuation; it was laid open, and purulent matter, to the extent of nearly two pounds, was discharged! In this case, which we know to be authentic, ignorance was as conspicuous as barbarity. Such a scene could hardly occur in these days, and we heartily trust it never may in those which are to come.†

34. *Paralysis*.—Palsy is frequently pretended among mendicants, and it is also occasionally

* Méd. Légale, t. ii. p. 471.

† See Med. and Phys. Journ. for January 1808, vol. xix. p. 1.

* Op. cit. p. 473.

feigned in the army and navy. The pathognomonic symptoms of palsy commonly involve some organic alteration, which it is scarcely possible for a man to simulate with success if his case be carefully investigated by well qualified persons. The fact, however, that impostors have been successful, is a sufficient warning to medical practitioners to devote much attention to the examination of doubtful cases. Coche, a French surgeon, who has given much of his attention to feigned diseases, says, "la simulation de cette maladie (palsy) n'est que ridicule;" but experience has proved that, however ridiculous, it has often been successfully practised. Dr. Cheyne mentions several cases of this kind, in two of which the pretended paralytics evinced ludicrous proofs of their still possessing the use of their limbs immediately after they had succeeded in gaining their discharge. It ought always to be considered a very suspicious circumstance in a soldier or sailor if the loss of power is confined to a single limb, as the arm, as such a form of paralysis coming on in adults is extremely rare. In a case detected by Dr. Cheyne, his opinion of the disease being feigned was chiefly founded on the following considerations: because there co-existed no other signs of disease; because the countenance indicated health and intelligence; because the function of the brain was undisturbed, and all the senses were entire; because paralysis of the arm is a complaint frequently feigned by soldiers, but very rare in reality.

Feigned paralysis has been frequently detected by subjecting the patient to a powerful electric shock. A case occurred in the New-York state prison which resisted all medicines until this remedy was tried. Upon receiving the shock the patient jumped up, ran into the hall, and asked for his discharge from the hospital.* Mr. Hutchinson detected an imposition of this kind in a sailor, by administering a dose of opium to the patient, and then tickling his ear during sleep; to relieve the irritation "the paralysed hand was instantly raised to the ear, which he rubbed with no small degree of force, and then turned round upon his left side, dragging the bed-clothes over him with his heretofore useless arm." Of course the discovery was complete. The editor of the journal in which Mr. Hutchinson's essay first appeared mentions a similar case in a soldier detected by the same means: in this case the sound arm was previously bound down to the side, under pretence of thereby benefiting the disabled limb.†

Shaking palsy is simulated chiefly by mendicants. When the general health appears to be good, little attention need be paid to the shaking. For the diagnosis of this disease see the article PARALYSIS.

35. *Phthisis*.—It could scarcely have been imagined, *a priori*, that a disease like phthisis, attended with such complexity of symptoms, and marked by such conspicuous alteration of the

external parts, would have ever been chosen as a subject of the malingerer. The following extract from Dr. Cheyne, however, will show that this has really been the case; and as this form of simulation has never come under our own view, we shall content ourselves with the remarks of this excellent observer:—"The soldier, not content with representing one feature of consumption, will often undertake a perfect portrait of that disease, and this he will sometimes execute with great cleverness. The thought would seem to strike him while in hospital under treatment for catarrh, or recovering from fever accompanied with pulmonary irritation. His cure all at once seems suspended; his food, he says, *stuffs* him, and he begs to be replaced on spoon or milk diet; he coughs much at the period of the daily visit; he suppresses his cough for some time previously, so that if there is any defluxion, it may be expectorated at that period. He expresses a wish to be let blood or blistered for a pain of the chest; begs for some medicine to relieve his cough; applies for a furlough; in short, so well does he act his part, that unless the surgeon is very circumspect, he will discover, when too late, that he has been made a dupe of."*

It is needless to observe that a thorough acquaintance with all the phenomena of the real disease will enable any one, who is on his guard, to detect an imposition of this kind. Auscultation will be, in such cases, a most powerful, and frequently an infallible means of ascertaining the truth.

36. *Polypus of the nose*.—This has been imitated by the matchless ingenuity of the French conscripts, by introducing the testes of cocks and hares' kidneys into the nostrils.†

37. *Pompholyx*.—This affection of the skin is sometimes simulated by the application of blistering-plaster. The imposture may often be detected by carefully examining the vesicles, as parts of the flies are apt to adhere to them. In a young woman who lately produced this affection in order to retain her comfortable position in an infirmary, this was the case; and, upon examining her box, small fragments of blistering-plaster were found secreted.

38. *Pregnancy*.—An impregnated state of the uterus is sometimes pretended, to gratify the wishes of relations; to deprive a legal successor of his claim; to extort money; to obtain remission of labour; or to delay the execution of punishment. A medical practitioner, who has to give an opinion on a doubtful case of pregnancy, would require to make himself intimately acquainted with the signs of real pregnancy, and he ought especially to consult the best works on legal medicine. Auscultation promises to be the most successful means of discovering whether an alleged case of pregnancy be real or merely pretended. (See AUSCULTATION.)

Pregnancy is very frequently feigned by negro slaves in the West Indies with the view

* Dunlop's *Beck*, p. 12.

† Med. and Phys. Journ. vol. liv. p. 93.

* Loc. cit. p. 160.

† Percy and Laurent, op. cit.

of obtaining ease; as masters are accustomed to indulge them, when pregnant, with repose from the severer kinds of labour. Besides the assumption of the sickness and other common symptoms of pregnancy, they place pads on the abdomen to deceive the sight. When they apprehend a discovery, they pretend that they have had an abortion, and often speedily recommence the same course of deception. They know by experience that it is an easy matter to feign the early symptoms of pregnancy. A case of simulation of this kind, which was carried to a very refined pitch, was mentioned to one of the writers of this article by the gentleman on whose estate it occurred. A female, whose repeated alleged abortions had excited the suspicion of the overseer, and who was in consequence assured that nothing short of ocular demonstration would obtain belief, had the ingenuity to mutilate and prepare a lizard so as to deceive her cunning inquisitor. This imposition, however, was afterwards completely detected. These pretended *gravidae* are occasionally locked up some months before the expected period of delivery; and instances have been known where they have remained confined for many months after this period has passed.

39. *Prolapsus ani*.—This disease has been simulated by partially introducing into the anus a sheep's bladder or gut containing blood, leaving a portion externally to represent the prolapsed rectum. Ambrose Paré mentions a case of this kind; and the authors of the article in the *Dictionnaire des Sciences Médicales* another.

40. *Rheumatism, Lumbago, &c.*—This class of disabilities is frequently feigned by the members of benefit societies, and by soldiers and sailors when they wish to evade a particular duty or to procure their discharge. Rheumatism, when severe, is commonly marked by some functional derangement or organic alteration, which it is difficult to simulate successfully. With respect to soldiers and sailors they ought very rarely to be discharged on account of alleged rheumatism, &c. &c. unless in cases where there is an obvious organic change, such as great extenuation of a limb or nodosity of the joint. As in the case of simple pain, it is often difficult to discriminate these fictitious cases of rheumatism from the real disease. Still an attentive observer will in most cases be able to detect the feigned disease.

The following remarks by Dr. Cheyne on this subject are very judicious, and well deserving the attention of military and naval practitioners: "Chronic rheumatism is distinguished by some disorder of the digestive organs, impaired appetite, a look of delicacy, a degree of pyrexia in the evening, yielding in the latter part of the night or early in the morning to perspiration. Some emaciation, wasting of the muscles of the affected limb, fulness of the veins, and puffy enlargement of the affected joint, take place. There is in general an increase of the temperature of the affected part. These symptoms are much influenced by the state of the weather, and they

in some degree yield at length to proper treatment; whereas those who feign this disease usually retain their appetite and looks; have no diurnal return of fever, and no inflammatory symptoms. They give a glowing account of their sufferings, alleging that they have entirely lost the use of the part affected, which seldom happens in genuine rheumatism. There is for the most part no adequate cause assigned for the complaint; no relief from remedial treatment is acknowledged; and while real rheumatic affections are aggravated by damp, the impostor consents equally at all times."^{*}

41. *Short sight*.—This being a state of vision easily feigned, and, when real, incapacitating the subject of it for the duties of a soldier, is one of the most common disabilities pretended by unwilling recruits. It is also assumed by soldiers in order to obtain their discharge. During the operation of the French conscription, and particularly in the early part of it, before effective means of prevention were taken, short-sightedness was feigned to a singular extent by the young conscripts. In the department of the Seine, of every thousand conscripts who were exempted from service in consequence of disabilities, from the year 1800 to 1810 inclusive, fifty-eight were excused in consequence of being near-sighted. At last the alleged disability became so common that a law was passed forbidding men to be exempted on this ground; and all such persons were ordered to be employed as pioneers, hospital-servants, &c. Besides being assumed where it does not exist, this defect can be produced by the habitual use of concave glasses; and this practice was extensively adopted by the young men in France liable to serve. In short-sighted persons, the *crow-feet* wrinkles at the corner of the eyes are strongly marked, and there is an habitual frowning or knitting of the brows; but these signs are by no means unequivocal. The surest tests are enforcing the employment of concave glasses suited to the exact degree of imperfection assumed by the simulator, and putting him to read a book quite close to the eye. If able to read a book in this position *without* the glasses, and unable to read with the proper glasses at a corresponding distance, we may be almost certain that the disability is feigned. And yet even in this we may be mistaken. MM. Percy and Laurent mention a young schoolmaster, who, in expectation of being some day drawn for the army, practised reading with all kinds of glasses before hand, and when he was drawn he obtained his exemption without difficulty. When any doubt is entertained regarding the existence of this defect, the most advisable measure is to follow the example of the French government, and place the individuals in situations where long vision is less necessary. This disability is rarely feigned by sailors, because, if real, it would not incapacitate them for the duties required of them.

42. *Somnolency*.—Occasionally persons al-

^{*} Op. cit. p. 175.

lege that they are unable to undergo any fatigue, and sometimes that they are incapable of muscular motion on account of a constant and irresistible sleepiness. Dr. Hennen has recorded a most obstinate case of this kind.* Another case is detailed in the *Edin. Ann. Reg.* vol. iv. The subject of this case was a soldier in the Somerset militia, and only eighteen years of age. He had been confined for desertion. From the 26th April to the 8th July, 1811, he lay in a state of apparent insensibility, and resisted every means which it was deemed advisable to attempt for the purpose of rousing him. These means consisted of thrusting snuff up the nostrils, electric shocks, &c. &c. It was at last conjectured that the torpidity might be owing to a fall, whereby his head might have been injured, and the operation of dividing the scalp was performed for the purpose of ascertaining whether there was not a depression of the cranium. The requisite incisions were made, the scalp was drawn up, and the skull examined without a word of complaint. When the instrument destined to scrape the bone was applied, he once, and only once, uttered a groan. As this case seemed to be hopeless, the man was discharged and conveyed to his parents. Two days afterwards, he was seen two miles from home, cutting spars, and carrying reeds up a ladder.

The following case of feigned somnolency, or loss of sense, is a good example of the obstinacy with which the symptoms of disease may be simulated for the purpose of avenging an injury, or to obtain unjust compensation. A clergyman hearing his wife and servant-maid disputing in the kitchen, went below, and interfered so far as to repel some rudeness offered by the girl to her mistress, which he did by pushing her to one side. The girl fell against the dresser, either by accident or design, whereby she received a slight contusion over her eye. She then ran to the street-door, and told the people that she had been almost murdered by her master; and to corroborate this assertion, she fell apparently into an epileptic fit. Shortly afterward she was conveyed, as one expiring, to an hospital, and the clergyman and his wife were dragged to jail. The windows of his house were broken, his furniture was thrown into the street, and an account of the dreadful murder cried over the whole town. The girl lay for ten or twelve days without showing the least sign of sense or recollection. Mr. Dease having been called into consultation, soon detected the imposture, and the woman almost immediately disappeared. The terror and shame of being so publicly exposed made such an impression on the mind of the clergyman that his life was brought into the most imminent danger, and the expenses attending his confinement greatly injured his fortune.†

Somnolency is, however, a real disease, and

may originate without any obvious cause as a symptom of other diseases, or from external injury. Persons whose minds are alienated will frequently remain in bed for several weeks together in a semi-comatose state, resisting every argument and intreaty. This fact, and the following histories of real somnolency, will teach the medical officer to be extremely cautious in pronouncing any such apparent affection to be simulated.

Rudolphi, when in Milan, in 1817, witnessed the case of a journeyman book-binder, nineteen years of age, who was affected with a curious sort of sleepiness, in some degree resembling intoxication. In Rudolphi's presence he fell asleep, although he still continued to fold sheets along with the other workmen. His eyes were shut, and when it was wished to excite his attention, a loud knock was given on the table, by which he was awakened, and then he answered questions. The voice of one of the workmen, who was his friend, excited his attention, even when the tone was low. Upon being partially roused, he looked about with his eyes half open, and seemed to be aware of what was going on around him; for example, when a sheet was purposely folded wrong and given to him, he appeared to be displeased. He wrote a note in Rudolphi's presence. His comrades used sometimes to lead him about when he was asleep, and to make him play at billiards, &c.; but he did not recollect that he had been so employed after he awoke. When allowed to remain asleep for a few hours, he began to snore, nodding his head as many persons do when asleep.

A strong and active hussar, after many an ineffective effort during eight months to rouse him from a state of somnolent listlessness and inattention to his person and duties, was discharged from his regiment, being generally considered as a *skulker*. Being forwarded to Chatham, he came under the care of Dr. Burrell, of the 72d regiment, who, from an absence of every other symptom of disease, was at first led to adopt the same opinion. In the course of a week, however, some difficulty of articulation was discoverable, greater heaviness in his look and sluggishness in motion appeared, which in a few days ended in coma, convulsions, and death. On dissection, two tumours of a firm medullary structure were discovered, in contact with each other, one of the size of a pullet's, the other of a pigeon's egg, situated in the right hemisphere of the brain, and projecting considerably beyond its surface.*

A seaman belonging to one of His Majesty's ships fell from a considerable height, and pitched upon his head: on examination, no fracture or depression could be discovered, the only mark of injury being a tumour of the integuments, which soon disappeared. From the moment of the accident, however, the patient exhibited symptoms of coma, inatten-

* Dub. Hosp. Rep. vol. iv. p. 138.

tion to surrounding objects, &c.; and he was therefore bled largely, purged, &c. The soporose state continuing without any other marked symptom, and there being discoverable not the slightest inequality of the bone, or other local indication of any injury beneath, the surgeon began to suspect imposition, and had recourse to the most vigorous counter-irritation, by blisters to the head, &c. partly on account of the painful impression produced by these means. This man at length was invalided, and on his way to England was seen by the gentleman to whom we are indebted for this interesting history, in the Naval Hospital at Gibraltar. At this time he lay in a listless semi-comatose state, rousing up when spoken to, opening his eyes and answering questions very rationally. A very marked symptom in this case was the incessant action of the left hand in alternate flexion and expansion, a symptom which had come on immediately after the accident, and had never since left him by day or by night. When the hand was restrained he seemed more uneasy, and as soon as it was disengaged the motions were resumed. He was sent to some of the naval hospitals in England, and his subsequent history is not known until he came under the care of Mr. Cline in May 1800, in St. Thomas's Hospital. At this time, says Sir A. Cooper, he was in a great degree destitute of sensation and of voluntary motion; his pulse was regular, his fingers were in constant flexion and extension. *He had a depression near the superior edge of the left parietal bone.* Mr. Cline trephined him, removing the depressed portion of bone, and the man gradually and completely recovered.*

43. *Syncope.*—A most disagreeable part of the duty of the medical officer is to attend at the corporal punishment of soldiers and sailors. On these occasions it is not rare for the culprit to feign fainting, in the hope of having his punishment remitted; and the medical officer is sometimes called on to decide. In other circumstances, also, syncope is simulated by soldiers and sailors with the view of obtaining particular ends; and it is occasionally the resource of the mendicant to impose on the charitable.

Except in the extremely rare case of persons having a voluntary power over the action of the heart, there can seldom be any difficulty in discriminating the fictitious syncope from the real. The total suppression of the pulse, or its great diminution in point of strength and volume, the coldness of the surface and of the perspiration, the paleness of the countenance, cannot be assumed at will; and without these, the seeming exhaustion or alleged loss of muscular power will not impose on any person of experience. The state of the countenance alone suffices to indicate the real disease in almost every case.

It is hardly necessary again to inculcate on the mind of the young military or naval sur-

geon, that he must, in all cases where the slightest doubt exists, take the side of mercy. It is better that he should be a thousand times imposed upon, than that a fellow-creature should be punished while labouring under a severe disease, to say nothing of the risk of death occurring if the syncope is real.

44. *Swelled leg.* (Barbadoes leg.)—Tumefaction of the leg is sometimes excited by soldiers by putting a concealed ligature round the leg and letting the limb hang over the side of the bed during the night. There was a case not long since in Fort Pitt General Hospital, which was supposed by some of the medical officers nearly to resemble Barbadoes leg. This man had been sent home from India to be discharged. On admission into the hospital his thigh measured in circumference twenty-two inches and three-quarters, the calf of the leg seventeen inches and a half, and the ankle fifteen inches. Six days after the ligature had been discovered and removed, the thigh measured twenty inches, calf of the leg fifteen inches, and the ankle fourteen inches. Close examination will almost always detect the impression of the ligature in such cases, and the practice may be prevented by inclosing the limb in a box, or wrapping it in a marked bandage.

45. *Ulcers.*—The formation or irritation of ulcers by artificial means has been in all ages a fertile source of successful imposition to that class of persons who live by exciting the compassion and charity of the benevolent. In former times the more cunning and less daring vagrants imitated ulcers by fixing certain foreign substances on the skin, such as dry, shrivelled leaves, part of the skin of a frog, and even pieces of flesh. A curious case is quoted by Foderé from an old French surgeon, Pigray, of a young woman who presented herself to the king of France to be *touched* for a large open cancer of the breast, but which, although “*le mieux simulé et contrefaict qui se puisse voir*,” Pigray discovered to be a slice of *spleen* fixed on the mamma!*

The actual formation of ulcers has been much more practised, and in the compulsory military service of all countries has been often carried to a very great extent. This was particularly the case during the late war among the French conscripts, and in the army and navy of this country. The most common site of these artificial ulcers, indeed almost the exclusive site in the army and navy, is the leg, a place, no doubt, selected partly because their existence in that position effectually incapacitates the patient from military duty. These factitious ulcers are either formed entirely by art, or, which is the more common case perhaps, artificially aggravated into great and severe affections from slight sores occurring naturally, or from slight accidents. The means used to effect these objects are very various: vesicants, irritants, caustics, compression, friction, puncture, excision, &c. &c. Some-

* A. Cooper's Lectures, by Tyrrell, vol. i. p. 312.

* Foderé, tom. ii. p. 486.

times a portion of skin is cut out, and then some irritating substance, such as lime, arsenic, corrosive sublimate, tobacco, the skin of salted herrings, acids, &c. applied to establish the ulcer, after which it is kept up by milder kinds of irritation. Mr. Hutchinson says, that the use of mineral acids is most difficult to detect. There was an old woman, who lived contiguous to the recruiting depôt at Dublin, who had the credit of carrying on a great deal of business in this way among the recruits. Her applications appeared to be a mixture of quick-lime and soft-soap. But one of the most approved methods of operating is the firm compression of a copper coin against the tibia; and we have reason to know that this was the most common practice in the navy. Copper has always enjoyed a great reputation as acting injuriously on the animal body, and it is probable that this reputation has been the chief cause of its being employed to produce or aggravate ulcers, although its main effect depends on the mechanical impression produced by it. Mr. Hutchinson once found, in dissecting the leg of a sailor, which he had amputated for extensive caries of the tibia, a half-penny imbedded between the muscles, "nearly three inches from the margin of the ulcer," and which the man confessed to have thrust into the ulcer nine months before.* Friction with sand seems also to have been extensively employed to produce ulcers; a process termed in the flash language "*for-hunting*."† An experienced eye will readily distinguish between an ulcer of recent formation asserted to be old, and one really old; but it is not so easy to discriminate one of long standing, kept up by repeated slight irritation, from a natural ulcer. In some cases, after the establishment of the ulcer, so refined has been the imposition that a blister has been applied *round* it, with the view of producing the red glossy appearance possessed by the cicatrix of ulcerated parts. But the most distinguishing difference is the ready curability of the factitious ulcers, when secured from the tampering of the patient.

When once a soldier or sailor is suspected of keeping an ulcer open, the obvious means of the treatment are, seclusion if practicable, and defending the ulcer from injurious applications. The most common methods adopted by medical officers to effect this last object have been to seal the bandages, or to inscribe on them, after they are applied, coloured lines drawn along the limb in such manner that it would be impossible to re-produce them if the bandage were removed and re-applied. Even these precautions have not always been found sufficient. Some of Mr. Hutchinson's patients kept up mechanical irritation by means of pins thrust through the bandages. He was therefore under the necessity of locking up the whole limb in a wooden box contrived for the purpose, and this he found an effectual remedy.

46. *Vomiting*.—Some persons possess the power of expelling the contents of the stomach at pleasure, and thereby simulate disease of that organ. In 1828, a soldier was for about six months in the General Military Hospital, at Dublin, on account of supposed disease of the stomach, chiefly indicated by a frequent disgorging of his food. About the end of that period it was ascertained that, instead of losing flesh, he increased in weight, a circumstance which was considered conclusive evidence that he did not suffer under any material disease. He was forthwith discharged from the hospital, and we have ascertained that he afterwards performed his duty efficiently. Vomiting became epidemic in the hospital during the time this man was a patient, but it ceased as soon as he was returned to his duty. Percy, in his article on simulated diseases, in the *Dictionnaire des Sciences Médicales*, mentions the case of a drummer who for a long time deceived the medical officer of an hospital by ejecting the contents of his stomach. He could at pleasure regurgitate his food. In a quarter of an hour after he had swallowed soup, he used to return the whole, apparently with great pain and general distress. It was eventually discovered that he privately purchased solid food, particularly hard-boiled eggs, which he did not vomit, and the imposture was thus detected.

Mr. Hutchinson mentions a case of feigned, or rather of factitious vomiting in a sailor, which was produced by voluntary compression of the epigastrium. The vomiting returned periodically, and upon the cause being discovered, was at once prevented by securing the patient's hands. Mr. Hutchinson adds, that he is thoroughly convinced of the existence of this power in certain persons to excite vomiting by pressure on the region of the stomach whenever they please.* Dr. Cheyne says that vomiting is voluntarily produced by some persons by swallowing air and then eructating, in which process part of the contents of the stomach is brought up along with the returned air.† We are, however, cautioned by this distinguished physician not to be too hasty in deciding on the nature of vomiting in suspicious cases, as he himself confesses to have been in one case deceived by a pretended vomiting, and in another to have considered a case of vomiting as feigned which eventually proved fatal.

47. *Wounds*.—These have often been feigned when they had no existence; have been greatly exaggerated when slight; and have been artificially produced by the patient or with his concurrence, in a very aggravated form.

a. *Fictitious wounds*.—The pretence of being wounded when uninjured, or of being severely wounded when only slightly hurt, has ever been the resource and refuge of the coward in the day of battle. This practice has even been carried to such an extent as seriously to affect military operations. Cæsar, in his account of

* Loc. cit. p. 88.

† Dunlop, in Beck, p. 8.

* Loc. cit.

† Dub. Hosp. Rep. p. 165.

the blockade of Utica, speaking of the wounded in a skirmish wherein the enemy were driven with great terror into their entrenchments before the city, says, "qui omnes, discessu Curionis, multique præterea, *per simulationem vulnorum*, ex castris in oppidum propter timorem se recipiunt. Quâ re animadversâ, Varus, et terrore exercitûs cognito, buccinatores in castris et paucis ad speciem tabernaculis relictis, de tertiâ vigiliâ silentio exercitum in oppidum reducit."* In the official report of the capture of Tarragona by the French, in 1811, Count Contreras, the governor, complains of having lost a great many officers in the last defence by their having *feigned wounds* in order to avoid military duty.† "I have many times known," says Northcote, "cowardly lubbers during action come tumbling down the ladder with most violent groans and complaints, though, at the same time, they have received little or no hurt, and all I could do or say could not prevail on them to make a second trial of their courage, nor go up again till the action was all over. Nay, I have been told by those quartered at the same gun, that some dastardly fellows have actually put their feet or stood in the way of the carriage, on purpose to be hurt, that they might have a plausible pretence for going down to the doctor, which I must own I have great reason to believe, having sometimes met with such contusions in the legs and feet, occasioned (according to their own confession) by the carriage, but at the same time so slight as was scarce worth mentioning; though sometimes very violent, at other times there was scarce any injury or contusion to be perceived, notwithstanding the most grievous complaints of pain and uneasiness."‡ Very distinguished men have had the meanness to simulate wounds. In one of his expeditions, Gustavus Adolphus is said to have pretended that he had received a contusion in the leg from a musket-ball, and, as a proof of the fact, exhibited a red spot on his leg and a corresponding blemish on his boot, which refused to receive the usual polish.§

One of the writers of this article was requested to visit an officer for the purpose of examining a gun-shot wound, which he alleged he had received from the enemy in his left arm. Upon examining the site of the wound, no injury could be discovered, except an abrasion of the cuticle, about the size of a large pea. The injury seemed to have been occasioned by a pen-knife rather than by a bullet. Care had been taken to destroy the sleeve of the jacket, so that it was impossible to learn any thing positive regarding the alleged cause of the wound by examining the clothes. Officers have been frequently accused of feigning wounds or contusions after a battle with

the view of having their names recorded in the Gazette, or for the more sordid purpose of claiming a pension.

In a case of feigned wound without loss of continuity, which came under our own notice, the man had stained the part to represent the purplish yellow hue of ecchymosis on the decrease, alleging that the contusion had been received some days previously.

b. Factitious wounds. Mutilation.—The infliction of wounds by the individual, chiefly for the purpose of mutilation, is a practice which has prevailed in all ages and countries where military service has been forcibly imposed upon men. Mutilation was a frequent practice among the conscripts of ancient Rome, more especially during the decline of the empire; and it would appear that it is from the most common species of mutilation among them, viz. by cutting off the thumb (*pollicem truncando*) that our modern word *poltroon* is derived. At first this sort of mutilation exempted the individuals from service; but afterwards the law was altered, and in the prescribed levy from any district, two maimed recruits were only reckoned as *one*. Soldiers who voluntarily disabled themselves were branded and still retained in the service. Mutilation was very frequent among the French conscripts during the wars of the Revolution and the Empire; and the same regulation was eventually adopted in France among the Romans, viz., the retention in the service of all men whose mutilation could be proved to have been intentional. A species of mutilation very common among them was the extraction of the incisor teeth, or the filing them down below the gum, a condition of parts which prevented the soldier from biting off the end of his cartridge in loading his musket.

Mutilation has been very prevalent in the army and navy of this country; and the modes in which it has been effected have often been more than usually bold and severe. The wounds have frequently been inflicted during battle, or in a crowded barrack-room, with the view of giving greater plausibility to their alleged accidental occurrence. Frequently, however, more especially in the navy, the act of self-mutilation has been openly practised.

During the late war a naval officer went on board a merchant vessel at Yarmouth for the purpose of impressing seamen, and while on board said, jestingly, to a boy about ten years of age, that he would take him with some others; upon which the lad ran below, and immediately returned with one of the fingers of his left-hand cut off, exclaiming—"You can't take me now! My father cut off three fingers that he might not be pressed, and I have done the same!" A seaman in the Ambuscade cut off his thumb in the presence of his officers, in a sudden fit of anger and despair at being kept in the service at a time when some others were discharged; and several instances have come to our knowledge where seamen cut off the whole or greater part of their hands, with the

* De Bell. Civ. lib. ii. 35.

† Courier, July 30th, 1811.

‡ Northcote's Marine Practice of Physic.

§ Historical Sketch of the last Years of the Reign of Gustavus IV. of Sweden, p. 57.

avowed purpose of obtaining their discharge. Others, again, who have committed similar mutilation of their persons, have pretended that they were done by accident.

In many cases of mutilation the object of the men is two-fold,—to procure their discharge from the service, and to obtain a pension. The self-inflicted wounds of soldiers are most commonly produced by the musket; and they almost always pretend that they have been accidental. During the period of four years from 1824 to 1828, there were twenty-one soldiers pensioned in Ireland on account of injuries they had received in one of their hands by the explosion of their own muskets. Recent regulations in the army deprive soldiers of pensions who are disabled by such accidents, except they occur in the performance of military duty; and if the mutilation is proved to be intentional, the individuals are still retained in the service, although unfit for the ordinary duties of a soldier. Mutilation occurs in the army more frequently in the hands and fingers than in any other part of the body. In one regiment, however, where the practice became so far epidemic that nine cases of mutilation by the explosion of muskets happened in the course of six weeks, the lower extremities chiefly suffered. We have known a number of cases of mutilation occur among soldiers when they were on a visit to their friends; and little doubt could be entertained that the maiming was voluntary. The injury commonly occurred about one or two days before the expiration of the furlough.

Mutilation has been practised, but much more rarely, by parish paupers, with the view of obtaining immunity from labour. It has also occasionally occurred among slaves in the West Indies; but we have been told that their animal courage is seldom sufficient to prompt such bold measures.

There will rarely, if ever, occur any difficulty on the part of the surgeon in detecting the imposition in the case of wounds being alleged to exist when no wound has been received. In the case of self-inflicted wounds or mutilation, however, it will not always be easy to prove that they have been intentionally produced. The proof will rest sometimes on the nature of the wound, sometimes on the circumstances under which it is stated to have occurred, and sometimes on other collateral circumstances. In the case of a soldier or sailor it will often be a matter of great importance to the individual, that the decision come to is the true one; as it will frequently have the effect of obtaining for him his discharge from the service, and perhaps a pension, or of depriving him of both advantages, and perhaps entailing punishment also. In forming his opinion of the probability of the wound being self-inflicted, the surgeon will be guided by the consideration of the nature and extent of the wound, its situation, the nature of the alleged cause, &c. For instance, if the wound be of such a kind as renders it improbable that the patient either could or would have inflicted

it; if it be of great extent and *more* than sufficient to effect the object the perpetrator may be supposed to have had in view,—if it be in a part of the body to which the patient's hands, or an instrument wielded by him, could not have reached,—the probability certainly is that it is accidental. On the other hand, if these circumstances are reversed, and if the mode in which it is stated to have occurred is improbable or impossible,—if the alleged cause or instrument is ill calculated or not at all calculated to produce the effect,—the surgeon will be more disposed to regard it as voluntarily inflicted. The examination of collateral circumstances will often afford more positive evidence than grounds of a merely medical kind. The following case affords an example of both kinds of evidence. A seaman on board one of His Majesty's ships lopped off two of his fingers with an axe upon a post, in the fore part of the ship termed *the manger*, and in the confusion of the moment left them there. He then ran down into the hold, and uttering a piercing cry rushed on deck, exhibiting his mutilated hand, and asserting that he lost his fingers by the accidental collision of two water-casks. Here the character of the wound sufficed to disprove the truth of the alleged cause;—no collision of casks could produce so clear a wound, or so complete an amputation; still more certain evidence, however, the man's own stupidity afforded; for shortly after his two fingers were found on the manger, and lying near them the axe which had divided them.

The improbability or even impossibility of a wound being inflicted by the patient himself, is, however, no certain proof that it has not been inflicted intentionally; since the unhappy men have been known, like the ancient Romans, to assist each other in the perpetration of this partial suicide. Instances of this kind have been mentioned to us both in the army and navy; the wounds being produced both by fire-arms and cutting instruments. During the late war we remember an instance of a father cutting off one of his son's fingers to prevent him serving in the militia. There was a young convict on board the hulk for boys at Chatham, not long since, who placed his right arm over a space between two beds, and got a companion to strike the fore arm with a long piece of wood. Both the bones were thus fractured; and even after the arm had been put up in splints, he found means to displace the bones, and thereby prevented a perfect union.

In concluding this article, we cannot dismiss from our minds the possible impression it may leave on the minds of junior medical officers in the public service; whom we would guard, on the one hand, if possible, from suffering a spurious humanity to be detrimental to the interests of the army or navy, and, on the other, with even more anxiety, from the vain desire of acquiring temporary consideration by a stubborn and cruel incredulity, or by an affected

shrewdness in detecting imposture where no imposture may exist.

There are cases mentioned in the preceding part of this article, which shew, indubitably, that the simulation of disease has frequently been practised without the existence of any interested motive, indeed without motive of any kind; that there is, in short, a species of monomania of which this simulation is the characteristic. Such cases may occasionally be remembered with advantage.

But there is another consideration equally worthy of being entertained by all who do not wish the common feelings of a man to be lost in those of a mere disciplinarian. For notorious malingers we are in no degree disposed to plead; but when instances of deception become *frequent*, in any country, in any garrison or station, in any regiment, or in any ship of war, the question may very reasonably present itself—is there not something wrong in the arrangement of the place, in the government or administration of the particular portion of the community in which such frequent deceptions are resorted to;—something which, acting injuriously on the bodies or the minds of the men, is therefore not beneath the consideration of the medical officers of the establishment, who alone can appreciate the mischief, and by whose mediation alone it is likely to be remedied? The privilege conferred by their profession, of being *the friends of mankind*, is one which ought not to be willingly resigned.

The negro-slave, and the conscript of an imperial conqueror, may be equally placed beyond the pale of such considerations; but the British soldier or sailor ought never to be so: even the convict is not shut out from mercy. The condition of both soldiers and sailors has, during late years, been much ameliorated; and deceptions are less frequent both in the army and navy than of old. These amendments in their condition have often arisen out of the representations of enlightened and humane medical superintendents. Wherever, therefore, we repeat, the instances of imposture are numerous,—wherever these manifestations of discontent are frequent among men whose general characters afford an assurance that in ordinary circumstances they would not prefer pain and privation to duty; the circumstances in which such opposite and desperate resolutions are taken, should undergo the most scrupulous and fearless investigation. Such a duty is enjoined by an authority higher than any temporary authority to whom its performance may happen to be disagreeable.

(J. Scott.—J. Forbes.—H. Marshall.)

FEVER.—The word *fever*, derived from the Latin term *febris* (a derivative of the verb *ferveo* or *ferbeo*, signifying *to be hot*,) is applied to a class of diseases characterised by morbid heat of skin, frequency of pulse, and disturbance in the various functions.

In the Greek language, the word πυρεξία (from πῦρ, *fire*) expresses fever; hence the

origin of the term *pyrexia*, under which the ancient writers comprehended *fevers* and *inflammations*, a classification which has been retained by modern nosologists. It therefore appears that upon one symptom alone, *increased heat*, the nosological distinction of a very numerous and important class of diseases has been founded. Though this characteristic feature is very generally observed, nevertheless in some cases of fever, strictly so called, the heat of skin is not above the natural standard, sometimes even below it; from this circumstance, therefore, it is evident that other phenomena are necessary to constitute a febrile disease.

We know so little about the cause of the generation of animal heat, that no satisfactory explanation of its increase or diminution in fever has been given: it seems probable, however, from some experiments, that its evolution is intimately dependent on the condition of the brain and nervous system, and until physiological investigations shall unfold with greater certainty the mode in which animal heat is generated, the pathologist must be satisfied with the ultimate fact, that in febrile diseases there is generally, among other phenomena, increased heat.

There are some diseases, the symptoms of which are so characteristic, and so invariably present, that there is little difficulty in determining their precise nature and seat. The various organic inflammations—of the brain, lungs, intestines, &c.—are examples of this class: there are others of which the precise locality is either so varied or obscure, either as regards the symptoms during life, or, in many instances, on dissection after death, that we are unable to discover their nature. To this latter class fever properly belongs. It is true that in most cases of fever we can discover the existence of certain lesions, but these are too vague or indefinite to enable us uniformly to decide on the primary seat of the malady. It is more than probable that in what is usually called *idiopathic fever* there is alteration either of the solids or fluids, although its precise locality cannot in every case be detected; but without disease in either the one system or the other, we maintain that fever cannot exist.

It is too generally imagined that the primary disease which induces fever is essentially local inflammation. The application of this doctrine to the early stage of fever, we hold to be not only at variance with facts, but dangerous as to the practical deductions to which it leads. We know that irritation, far short of inflammation, is sufficient to excite feverish indisposition, more particularly at those periods of life at which the vascular system is easily excited by apparently trivial local or sympathetic disturbance, (for example, in infancy or childhood by dentition or intestinal irritation,) and that this feverishness disappears when the cause is removed. The paroxysm of an intermittent is induced by the peculiar effect of a malarian poison; in this disease, the whole phenomena of fever are well marked, but certainly few

will maintain that the febrile disturbance is the consequence of local inflammation. There can be little doubt that the error alluded to may in a great measure be imputed to the attempts to discover the cause or nature of fever in the various local lesions which are observed in fatal cases.

On the other hand, the important fact should ever be kept in view, that the primary disorder, whatever it may be, passes readily into inflammation, and that the lesions which arise in the progress of fever constitute the principal source of danger, and are in many instances the more immediate cause of death.

If we trace the early records of medicine, we find that the nature of fever has afforded ample field for discussion from the time of Hippocrates to the present day. Both the solids and fluids have been investigated, and arguments adduced in support of the opinion, that a morbid condition of either the one system or the other was the cause of fever.

The ancients possessing a very scanty knowledge of anatomy, either in its healthy or morbid state, and the secretions being evidently vitiated in the progress of fever, it was natural that a morbid condition of the fluids should, in the early ages of medicine, be considered as its primary cause. The humoral pathology was accordingly received as the only explanation or theory of fever, for many centuries. We find the early medical writers entertaining the idea, that the system waged war against something noxious within itself, and that in the attempt to expel the offending agent, a violent commotion was excited. By this plausible theory, the duties of the physician were restricted to assisting nature in her efforts to get rid of what was deemed injurious to the welfare of the body: in fact, fever was imagined to be a natural and salutary process, indispensably necessary to throw off whatever was noxious, whether generated within the body, or introduced by external causes. Some theorists, in their anxious desire to support this doctrine, endeavoured to deduce the term fever from the Latin verb *februare*, signifying to purge or purify, and by those who implicitly believed in this theory, the derivation was no doubt considered apt and appropriate. The application of the doctrines of the humoral pathology in explanation of the phenomena of fever, received much apparent confirmation from the circumstance, that in eruptive fevers, after more or less febrile disturbance, various eruptions appear on the skin. It was rendered still more imposing, when the chemical doctrines of Paracelsus and Van Helmont were first promulgated. These chemical philosophers imagining that in fevers the fluids possessed at one time an alkaline, at another an acid quality, conceived that an effervescence took place, which gave rise to a febrile paroxysm—an assumption which led to not a few fatal practical errors.

The idea that particular forms of fever depend on a morbid state of the fluids has been maintained by many pathologists in more re-

cent times. The vital fluid has been subjected to chemical analysis with the object of ascertaining the comparative difference in its component ingredients during fever: these researches tend to shew, that previous to the attack, the blood is materially altered in its properties, and that its constituent principles undergo progressive changes, as the disease proceeds.

This department of chemical pathology has been lately much elucidated by the experiments of Dr. Clanny, detailed in his published lecture on typhus fever, and also by the observations of Dr. Stevens, who states that on opening the heart in fatal cases of yellow fever, he found, instead of blood, a dissolved fluid nearly as thin as water and black as ink. In both sides of the heart the fluid was equally black, and throughout the vascular system all distinction between venous and arterial blood was completely lost. Dr. Stevens supposes that when the blood is found in this state, it is entirely deprived of its stimulating properties, and therefore unable to excite the heart or to support life. It is affirmed, also, that the changes in the blood take place in a certain determinate order. It first loses its solid parts and becomes thin; it is then deprived of its saline principles, and becomes black and vapid; and lastly, from its preservative elements being destroyed, it loses its vitality so as to be incapable of supporting life.

Dr. Stevens considers this diseased state of the blood as the first link in the chain of the morbid phenomena which constitute fever. He believes that the aerial poisons from which all pestilential diseases arise are attracted with the atmospheric air into the circulation, mix directly with the blood in the pulmonary system, and that this poisoned or diseased state of the whole circulating current is the cause of the subsequent morbid action in the solids. Similar views, with respect to the pathology of fever are gaining ground in France, in which country the doctrines of solidism have almost exclusively prevailed.

The study of the structure and functions of the human body, in its healthy as well as in its morbid state, being the most satisfactory method of investigating the nature of disease, and lesions having been discovered in various organs in those who have died of fever, the attention of pathologists has in later times been directed to the state of the solids, in the hope that the origin of fever might be discovered.

The locality of the disease, however, has been most warmly disputed; indeed there are few organs of the body which have not been fixed on as the seat of fever; from which it may be inferred, that the doctrines of solidism are as little likely as those of the humoral pathology, to explain every variety of this inscrutable disease.

The functions of the brain being almost invariably affected in fever, it was to be expected that the solidists would endeavour to trace its origin to the nervous system. We accordingly find, that towards the close of the

seventeenth century, Stahl maintained that the phenomena were the result of a general commotion in the system, in its endeavour to throw off a spasm induced by torpor of the brain and nervous system. This explanation, which, after some modifications, was adopted by Hoffmann, was the first attempt to assign to the brain an important share in the pathology of this disease. It formed the basis of the theory invented by Cullen, who believed that in fever certain causes produced collapse or diminution of the energy of the brain. The effect of this on the voluntary muscles and extreme vessels was universal debility, and spasm or constriction of the capillaries: the subsequent reaction of the sanguiferous system, however, had the effect of resolving this supposed spasm, and consequently removing the fever. The prominent importance the Edinburgh Professor assigned to the fictitious debility which was imagined to result from this unknown condition of the brain, notwithstanding his theory that there was an inherent protective power in the system by which this fancied weakness was to be overcome, has been followed by serious practical errors, by abstracting the young and inexperienced mind from the more acute forms of fever, and from those important local complications which very frequently take place in its progress. Besides, as Dr. Parr has remarked, in this system the production of spasm by debility is an isolated fact without a support, and the introduction of the *vis medicatrix naturæ* is the interposition of a divinity in an epic, when no probable resource is at hand.

It is evident that in the definition of fever given by Cullen in his nosology, he expressly discountenances the idea of primary local disease; consequently he only partially adopted the doctrine of solidism, his theory merely implying that the various exciting causes act primarily on the brain.

This doctrine prevailed not only in British but in many continental schools, till Dr. Brown, evidently to gratify a feeling of resentment, opposed it with great bitterness. He invented and publicly propounded with much plausibility an opposite theory, which had the merit of great simplicity. According to Brown, the living system is an organized machine endowed with an inherent principle of excitability, arising from a variety of internal and external stimuli, and from which the excitement which constitutes the life of the machine is maintained. Upon these principles he founded the character and mode of treatment of all diseases, which were supposed to consist but of two families, the *sthenic* and the *asthenic*; the former produced by accumulated, the latter by exhausted excitability, and marked by indirect debility. The remedial plan was as simple as the arrangement. Bleeding, low diet, and purging were employed to cure the *sthenic*, and stimulants, of various kinds and degrees, the *asthenic* diseases.

Fevers, therefore, under this hypothesis, like other diseases, are either *sthenic* or *asthenic*, as they are the result of accumulated or of ex-

hausted excitability. This doctrine obtained few adherents in the British schools, though, as we shall presently notice, it prevailed extensively for a time in several parts of the continent, more particularly in the north of Italy.

Another class of solidists asserted that inflammation of the brain was the cause of fever. Ploucquet, who appears to have first taken this view, admitted, however, that from particular circumstances, other organs became occasionally implicated. Though this theory evidently implied that fever was dependent on local inflammation, it gave the disease a wider range—it assumed inflammation of the brain to be the source of fever, but that from the operation of certain causes, other irritations were in some instances superadded. Marcus and Clutterbuck have subsequently adopted this view, and have severally adduced arguments in its favour. Admitting, however, that the various exciting causes of fever do in some instances exert their action on the brain, we have no evidence that they produce, in the first instance, inflammation in this organ: on the contrary, the symptoms denote that the nervous system has only received a peculiar and powerful impression. When, on subsequent reaction taking place, a general impulse is given to the circulation, and the nervous system is roused from its depression, inflammation of the brain does frequently take place, especially in young plethoric subjects, just as it may supervene in any other organ to which, from causes hereditary or acquired, the individual may be predisposed. It should also be impressed on those who are inclined to adopt this doctrine, that although in a considerable proportion of persons who die of continued fever, the membranes, and frequently the substance of the brain, bear unequivocal marks of inflammation, yet such morbid appearances are by no means invariably observed.

We are next to advert to the doctrine which ascribes the phenomena of fever to primary affection of the intestinal canal. Lesions of the intestines in fatal cases of fever had been long ago pointed out by those who devoted much attention to the study of morbid anatomy. Bonetus stated that on dissection of persons who died of malignant fever, he found the stomach and intestines inflamed. Bartholinus made a similar observation; and in the works of Sydenham, allusion is made to ulceration of the intestines in continued fever. Subsequently Ræderer and Wagler* published a description of an epidemic mucous fever which prevailed at Gottingen, in which the appearances which were found after death in the alimentary canal are minutely detailed.

From these statements, it appears that the morbid appearances in the alimentary canal had attracted the attention of pathologists long before the promulgation of the theory in France, that fever was the result of inflammation of the mucous membrane of the intestines. This view, which was first maintained by

* De Morbo Mucoso, Goettingæ, 1762.

Broussais more than twenty-five years ago, has become the prevailing opinion in France, though it has gained comparatively few proselytes in other countries.*

Those who maintain the physiological doctrine of Broussais, contend that fever is entirely symptomatic of irritation or inflammation of the mucous membrane of the intestines. The leading principle of this theory is, that every irritation which is capable of producing an impression on the brain is reflected by this organ on the mucous membrane of the bowels. Broussais applies it to other acute diseases; for instance, in small-pox or measles, the inflammatory excitement by which they are accompanied is supposed to be first conveyed to the brain, and afterwards reflected on the mucous membrane of the intestines, and that thus inflammation (gastro-entérite), the supposed cause of these eruptive fevers, is produced.

It is affirmed that inflammation and its consequences are invariably found in the mucous lining of the intestines on examination of persons who have perished from fever, and that the treatment which is founded on this view is the most successful. Broussais, indeed, asserts with unparalleled boldness, that the tables of mortality declare in favour of the new doctrine, and that its influence on the population would be more favourable than vaccination itself.

Though Röederer and Wagler, Prost,† Baillie,‡ and others had previously detected morbid appearances in the bowels in their dissections of persons who had died of fever, the theory of Broussais, that inflammation of the mucous membrane of the intestines is the cause of fever, had the effect of directing the attention of pathologists still more particularly to the condition of the intestines in this class of diseases. In 1813 M. Petit and M. Serres§ published the account of a disease, very frequent in Paris in 1811, 1812, and 1813, which they called entero-mesenteric fever, and which was characterised by all the symptoms of continued fever, but originated apparently in certain changes in the inferior portion of the small intestines and ileo-cæcal valve, accompanied with enlargement and suppuration of the corresponding glands of the mesentery. The precise anatomical lesion of the intestines, however, was not ascertained by these laborious pathologists, but subsequently by M. Bretonneau of Tours,¶ who, after investigating the subject with great minuteness, came to the conclusion that the

primary source of fever was in the conglomerated mucous follicles, or glands, situated in the lower portion of the ileum and solitary glands of the cæcum.

A most full and elaborate work has been lately published by M. Louis,* in which the pathological views of Petit, Serres, and Bretonneau as to the primary seat of fever are confirmed. This author, moreover, has given a most minute account of the various secondary lesions which supervene on this supposed primary intestinal disease.

These views of the nature of fever now prevail almost exclusively among the French pathologists. Mild fever is supposed to arise from gastro-enteritis alone, the various forms which it occasionally assumes being regarded as gastro-enteritis, with particular complications. For instance, inflammatory or ardent fever (a form rarely observed) imports an intense degree of this lesion; the adynamic (typhus mitior) is regarded as gastro-enteritis which has assumed such a degree of intensity that the general powers decline, while the intellectual functions are more or less disturbed. The more malignant forms of fever (typhus gravior) are supposed to be gastro-enteritis complicated with irritation of the brain, from sympathy with the state of the alimentary canal; and when fetor of the breath, perspiration, and stools are observed, the disease becomes what has been termed putrid fever,—that is, putrid symptoms are superadded to the primary gastric inflammation.

It cannot, however, be conceded that in every form of fever this local disease does exist, as it has not been universally, nor even in the majority of instances, discovered on the most minute examination of the intestines in fatal cases. The more probable inference is, that this gastro-entérite, or follicular disease, occurs only occasionally, and that it is much more common in some places than in others. We know that it is observed more frequently in the fevers of France than in those of Britain; very rarely, if ever, in the epidemic fever of Ireland; and that it is only occasionally met with in the epidemic visitations in the northern districts of England and Scotland.

From its being observed in a greater proportion of cases in London and Manchester, it is probable that there are some local causes or circumstances in particular places which produce this intestinal affection. Whether in those cases in which it has been found after death, (for we maintain that the pathognomonic or diagnostic symptoms by which it has been supposed to be indicated are by no means uniform or satisfactory,) it be the cause or effect of the febrile symptoms by which it is accompanied, is still a question about which there is great difference of opinion, though the majority of British physicians regard these intestinal lesions as only the sequelæ or consequences of fever.

¶ *Trousseau, de la Maladie à laquelle M. Bretonneau a donné le nom de dothin-entérite*. Arch. Gén. de Méd. X. 67, 1826.

The assertion that the treatment founded on the gastro-enteric pathology is the most successful, is only an assumption; indeed, it may be fairly inquired how many hundreds annually survive the treatment calculated to increase gastric inflammation—how many are daily stimulated with bark, wine, and ammonia, and yet recover? Besides, how can this doctrine be applied in explanation of the phenomena of intermittent fever? In France as well as in this country, periodic fevers are successfully treated by stimulants—bark, and even arsenic; not to allude to the complete suspension of the febrile paroxysm for twenty-four, forty-eight, seventy-two hours, or even longer.

These circumstances, when duly weighed, must in our opinion disprove the general conclusion, that every form of fever is the result of gastric inflammation. On the other hand, we are bound to admit the occasional existence (more frequent in some localities than in others) of the various intestinal lesions, which have been so minutely and elaborately described by the French pathologists, to whom, if this discovery be not entirely due, the merit must be conceded of having, with indefatigable labour, followed up the few hints which previous writers had thrown out, and thus brought to perfection one of the most important pathological facts connected with the morbid anatomy of fever.

The celebrated Pinel took a more extended view of the nature of fever than any preceding writer of the continental school. He distinguished symptomatic from primary or essential fevers, and comprehended under this latter class, acute diseases in which there is a quick pulse, hot skin, and disorder in the various functions, the symptoms being independent (as he supposed) of local disease. While he admitted, however, in his classification, the existence of fevers without primary disease in any organ, he evidently localised the varieties when he stated that the seat of inflammatory fever (*angio-tenic*) was in the organs of circulation; that the origin of bilious fevers (*meningo-gastric*) was in the mucous membrane of the intestines; that a particular form of gastric fever (*adeno-meningeal*) depended on disease of the mucous follicles alone; that in another variety (*ataxic*) the brain and nervous system were chiefly affected; another type (*adynamic*) being characterised by great prostration or depression of the vital powers, and often complicated with symptoms which have been usually referred to putridity.

These views have been since partially adopted, and have evidently given origin to the doctrine entertained by a large proportion of physicians of the present day, that fever is an essential disease, that is, the symptoms are independent of primary organic lesion; though it is admitted that in the majority of cases, local inflammations become developed in its progress, and constitute the principal source of the severity or danger of the disease.

The doctrines of Brown, which had obtained, as we have stated, comparatively few

converts in his own country, made a strong impression in the north of Italy. Rasori, who had visited the medical school of Edinburgh, was so enamoured with the Brunonian system, that, on his return to Italy, he published a compendium of this system, (to which the learning and ingenuity of Darwin had given a new impulse,) as well as a translation of the celebrated *Zoonomia* of Darwin.

A few years afterwards, however, a petechial fever appeared at Genoa, in which the stimulating treatment recommended by Brown was evidently so injurious and positively fatal, as to induce Rasori to reconsider the theory. He then became convinced of its inconsistency and error, and ultimately acknowledged this conviction in an account which he published of the epidemic of Genoa.* This epidemic, from whatever causes it arose, had many of the characters of what Brown termed an *asthenic* disease, and was consequently treated by stimulants. From the numbers who perished under this plan, and from observation of its symptoms and progress, during which local inflammations not unfrequently occurred, Rasori was induced to substitute a modified anti-phlogistic, or, according to the language of the Italians, a *contro-stimulant* treatment.

Bloodletting in the commencement of the disease, when the patient was young and vigorous and when the symptoms demanded it, was found decidedly beneficial; and in less severe cases, saline purgatives, antimonials, (more especially the tartar emetic in liberal doses) and acidulated drinks were employed.

These remedies, with blisters in the advanced stage, stimulating friction to the abdomen with the view of allaying the gastric irritation, light bed-clothing, and rigorous diet, constituted the treatment employed in the epidemic.

This change of Rasori's opinions produced a considerable sensation, and had the effect of overturning the leading principles of Brown's system in Italy. The professors in the north of Italy, who were formerly attached to Brown's views, taught the doctrines of Rasori with some unimportant modifications, and ultimately several works emanated from the different universities, explaining the leading principles of the "Doctrine of Contro-stimulus," or as it was afterwards termed, the "New Medical Italian Doctrine." As it would lead to digression, we must refer those who wish to obtain information on the Italian doctrines to the several works alluded to.†

* Storia della Febre Petechiale di Genova. Del Profess. Giovanni Rasori.

† Prima Linia Materie Medicæ, Auctore Syrus Borda.—Della Nuova Medicina Italiana, Proluzione alle lezioni di Clinica Medica nella P. Università di Bologna per l'anno Scholastico, 1816-1817. Del Professore Giacomo Tommasini.—Dell' Infiammazione et della Febre Continua; considerazioni Patologico-Pratiche. D. G. Tommasini, Pisa, 1820.—Del Metodo di curare, &c. Del Profess. Giacomo Tommasini. Bologna, 1821.—Lezioni di Terapea Speciale sulle Infiammazione, e Rendiconto Clinico, di V. Mantovani, Pavia, 1820.—Institutiones Pathologicæ. Auctore, F. A. Fanzago.

Tommasini, whose learning and reputation rank him as a leading authority of the Italian school, considers fever to be the immediate result of a morbid condition of some internal organ; and in this he is followed by a large majority of the Italian physicians.

Others, however, adopt the views of Rubini, and ascribe the phenomena of fever to the effect of a contagious principle absorbed into the circulation, which, after producing inflammatory action, gives rise to symptoms indicating failure of the powers of the system. The antiphlogistic treatment is consequently pursued in the commencement of the fever, and afterwards a stimulant plan, when the powers of the system appear to give way.

The doctrines of Broussais have obtained an inconsiderable number of adherents in Italy, so that we find the views of this celebrated pathologist are much more generally received in France than in any other country.

In our opinion, both essentialists and localists have taken a much too limited view of the etiology of fever. It appears to us that fever, whatever be its form, depends on some modification of one or other of the elements which enter into the composition of the human body, or in other words, that it follows as a consequence of a morbid condition of either the solids or fluids.

We know that, when the function of any organ becomes seriously disturbed, more particularly if inflammation arise, fever is induced. It is probable that the various external causes, terrestrial or atmospheric poisons for example, induce fever by their action on particular parts, in the same way as the different poisons are known to affect particular structures. On this principle the symptoms peculiar to some epidemics may be explained; for instance, catarrhal fever, in which the mucous membrane of the air-passages is affected; or gastric fever, in which a peculiar impression seems to be made on the mucous lining of the intestines.

We shall endeavour to shew, in treating of the pathology of the fluids, that the blood is not only materially changed in fever, but that the diseased state precedes the attack, and that the changes take place in a determinate order. This view is corroborated by Andral, who states "that the fever termed *inflammatory* seems often to arise from no other source than the blood being too rich in fibrine; in like manner, an impoverished state of the blood, whether accidental or natural, is often connected with *mucous* fevers, and with those characterised by a sudden sinking of the vital powers; and that the source and primary seat of *typhous* fevers, properly so called, is proved to be in the blood, inasmuch as they are caused by the introduction of deleterious substances, such as animal or vegetable effluvia, into that fluid."

It is in this way only, by the blood becoming contaminated and in this state circulating through the system, that fever can be supposed to be, according to the language of Dr. Fordyce, "a general disease which affects the whole sys-

tem, the head, the trunk of the body, and the extremities; the circulating, absorbing, and nervous systems; the skin, the muscular fibres, and the membranes; the body and likewise the mind."*

When putrid substances are injected into the blood of the lower animals, this fluid loses its power of coagulating, and acquires a rapid tendency to decomposition: great sensorial disturbance, convulsions, delirium, hurried breathing, and bloody exhalations also take place, followed by speedy death; and if the poison injected be highly concentrated, the animal is almost instantly destroyed.

The effects which follow from the use of food of an unwholesome quality, or from an insufficient quantity of food, are probably owing to the changes which the blood undergoes from these causes; hence scarcity may act both as a predisposing and exciting cause of fever. In this way, the origin of the disease in times of general distress among the poor is readily explained; and the history of epidemic fevers in Britain shews the intimate connexion that has always subsisted between scarcity and fevers of a low or malignant type.

It is also extremely probable, that in fevers which are produced by living in an impure atmosphere, the blood becomes the medium by which the morbid matter is circulated through the system. To prove the effect of putrid emanations on the animal economy, Majendie confined a healthy dog in a situation which exposed him to putrid miasmata. For the first four days there was no change; he then began to emaciate, and died much attenuated within six. Majendie imputed the death of the animal to the effect of the miasmata he respired and took with his food. On opening the body, which was much emaciated, the mucous membrane of the bowels was found inflamed.

CLASSIFICATION OF FEVERS.

Pyrexia, or febrile diseases, have been divided into two great classes,—FEVERS and INFLAMMATIONS. In the present article, we shall consider the first class only, referring the reader for the consideration of the second, viz. symptomatic fevers (inflammations), to the separate articles in the work.

The different forms of fever have received various distinctive appellations, founded on their supposed causes. We accordingly find in systematic works various subdivisions,—*camp, hospital, prison, or jail fever*. Others have preferred, as a ground of distinction, the peculiar phenomena which each type of the disease presents; hence the origin of the nomenclature, *inflammatory, bilious, nervous, malignant or putrid, petechial, typhoid, yellow fever, &c.*

The types of fever which are met with in temperate countries have been arranged according to certain phenomena observed in each. In one form, the symptoms or series of phenomena constituting the febrile paroxysm ob-

* Dissertations on Fever.

serve a continued or uninterrupted course; in a second, they do not follow a continuous course, but become either suspended for a definite period, or a considerable remission or abatement only takes place; in a third, the febrile symptoms are accompanied with a peculiar eruption, which, with certain symptoms, indicates a particular form of eruptive or exanthematous fever.

A classification of fevers, founded on these distinctive characteristics, being sufficient for every practical purpose, the following arrangement will be adhered to in the present work:—

1. Continued.
 - a. A simple.
 - b. Complicated.
 - c. Typhus.
2. Periodic.
 - a. Intermitting.
 - b. Remittent.
3. Eruptive, or
Exanthematous.
 - a. Variola.
 - b. Rubeola.
 - c. Scarlatina.

Before entering on the consideration of the varieties of fever, it will be proper to make a few observations on the phenomena which occur in a febrile paroxysm. The paroxysm consists of three stages,—the *cold*, the *hot*, and the *sweating*, which in general succeed each other in the order enumerated.

These terms have been given from the peculiar symptoms observed in each stage: thus in the *cold* stage, there is sensation of cold accompanied by shaking; the *hot* stage is indicated by increased heat; and the *sweating* stage, by the diaphoresis or perspiration which terminates the fit.

The successive stages which constitute a true paroxysm of fever are only observed in intermittent fever, in which there is a perfect intermission, or *apyrexia* between the fits. In continued, and in symptomatic fevers (inflammations), though there may be sensible abatement of the febrile symptoms at irregular periods, complete suspension of the disease for a definite time, as is observed in periodic fevers, never takes place. Though these diseases are often ushered in by a sensation of chilliness or actual shivering, almost invariably by morbid heat of skin, still the rigor or cold stage is so frequently unobserved, that it cannot be said to be essential either to the continued or symptomatic forms of fever.

The first symptoms of the *cold* stage denote a primary impression on the nervous system. This is evinced by the disinclination to exertion, and the evident feebleness or actual prostration. To these succeeds more or less restless uneasiness, which induces the patient to endeavour to obtain relief by frequent change of posture. This restless state is generally accompanied with more or less mental inquietude; hence the inability to fix the mind on any subject requiring continued attention. These are the sensations precursory to the rigor or shivering-fit, the first

indication of which is a feeling of chilliness: this may be general or only partial; for instance, it may be confined to one or more of the limbs, or to the loins, while the other parts of the body feel comfortably warm. The chilliness, after continuing some time, passes into tremor, which begins first in the lower jaw, and then gradually extending over the body, terminates in general muscular agitation. The tremor is often very severe; in some instances so violent, that according to practitioners who have witnessed the more intense forms of intermittent fever, convulsions have actually supervened; this, however, is to be regarded as a rare occurrence, at least in temperate climates. The skin feels cold, not only to the patient himself, but sensibly so to another person; and when the thermometer is applied, the temperature is found to be many degrees below the average standard of health: according to Dr. Wilson Philip, it has been observed as low as 74° Fahrenheit.

As the cold stage passes off, the skin becomes gradually warmer, though the patient is not always sensible of the change; hence, while he still complains of feeling cold, the skin often feels comfortably warm, or even warmer than natural, to another person.

The appearance of the skin in the cold stage indicates a deficiency of animal heat; the lips, nails, fingers, and toes, in fact those parts at a distance from the centre of the circulation, are pale and shrunk, while the skin becomes rough, resembling that of a fowl after it has been stripped of its feathers: hence the term *cutis anserina* has been applied to express this condition of the skin. The shrinking of the integuments is exemplified by the fact of a ring which fits the finger before the approach of the cold stage, becoming so loose as to fall off soon after it commences. It is also not uncommon for ulcers to dry up, or tumours to diminish in size, and even to subside altogether, while the cold stage of fever lasts: but when the hot stage becomes developed, the finger enlarges, so that the ring again fits tight, ulcers again discharge pus, and tumours reappear.

From the intimate sympathy between the nervous and circulating systems, there is in the cold stage of fever some alteration in the pulse. At the very commencement of the fit, before the rigor has come on, it is more feeble than natural; during the shivering it is small, quick, and occasionally irregular. The breathing is generally at the same time hurried, often suspirious, and the patient complains of tensive pain or constriction in the præcordial region.

When this unnatural state of the muscular, circulating, and respiratory systems has continued for some time, the mental functions not unfrequently become disturbed, indicated by the restlessness so common in almost every kind of fever, by some degree of confusion, and sometimes delirium, or even coma. In some instances the nervous influence of parts at a distance from the brain become impaired, as in the instance of some of the senses

becoming affected, or of the patient complaining of a sensation of numbness in the extremities.

The organs of secretion are at the same time more or less deranged. The patient is indifferent to food, and complains of thirst and of a disagreeable clammy state of the mouth. In some instances there is gastric disorder, manifested by frequent retching or vomiting, or purging of bilious fluid. This gastric irritation is, however, seldom observed in the periodic fevers of temperate countries, though in the bilious remittents of hot climates it forms a prominent character of the disease, and is not unfrequently attended with jaundice. The urine in the cold stage is limpid.

The analysis of the symptoms of the cold stage of fever proves the consecutive disturbance of the nervous, circulating, and secreting systems. It is, however, to be remembered that there is great difference in the intensity of the affection in the several organs; the prominent characteristic—the sense of cold, or even the rigor may be altogether wanting, or only represented by a degree of general indisposition, such as languor, chilliness, and sense of feebleness. This will be more particularly pointed out when irregular periodic fevers are noticed.

The duration of the cold stage of fever varies from half an hour to four or five hours, but there is every intermediate variety as to its length. It is often longer in the first than in the subsequent paroxysms, and shorter in remittents than in intermittents; so that, although its average duration may be computed between one and two hours, much depends on the type of the fever, its severity, and the climate in which it occurs. It is always longer and more severe in warm than in temperate countries; it may even be mitigated by the adoption of certain measures to be pointed out when we come to notice the treatment; but as a general rule, it has been observed that when the cold stage is short, the subsequent stages of the fever are almost invariably severe.

Though there is seldom any danger to be apprehended in the cold stage, it is proper to state, that under some circumstances, so great has been the shock given to the nervous system, that the vital powers have never recovered such a degree of energy as to produce reaction; indeed individuals have actually died in the cold fit.

The approach of the *hot* stage of fever is indicated by the chilliness or shivering subsiding, or alternating with warm flushings. The natural heat and colour of the skin then return, the shrinking and cutaneous constriction being succeeded by fulness, especially of the features, which in the beginning of the hot stage appear more turgid and animated than in health. This is followed by increased heat, which becomes gradually diffused over the body, the thermometer indicating an increase of several degrees above the ordinary average temperature of health, (varying from 100° to 105° Fahrenheit,) while the skin feels dry and parched. With these external changes, there are corresponding

alterations in the functions of the several organs: for example, the depression, stupor, or coma of the cold stage is succeeded by sensibility to external impressions, so that sounds or brilliant light are offensive; there is generally pain in the head, back, and limbs, and not unfrequently transient delirium. The breathing becomes more free; the pulse, from being small, feeble, and rapid, becomes more full and expanded, and the sense of præcordial constriction, which is so oppressive in the cold stage, subsides. In this accelerated state of the circulation, hemorrhage from various parts, more particularly from the nose, lungs, uterus, or bowels, is not uncommon. These evacuations of blood have generally been remarked to be salutary, by relieving local congestions, which are apt to take place in the hot stage of fever.

There is little change in the natural functions: there is perhaps more thirst; the urine becomes high-coloured, but on standing does not deposit any sediment; and should there have been much gastric disturbance during the cold stage, it generally abates or goes off entirely as the hot fit becomes developed.

The hot stage gradually terminates in copious perspiration. This constitutes the *sweating* stage, which is generally followed by great relief. The upper parts of the body first become bedewed with moisture, the sweating afterwards extending over the trunk and lower extremities. The sensorial disturbance now vanishes, the pulse resumes its natural tranquillity, the breathing becomes easy, and the urine in many instances deposits a sediment some time after it has been voided. The sweating, after continuing some time, disappears, but the patient remains weak and exhausted after the paroxysm has quite disappeared.

Though these three stages occur in regular progression in every well-marked paroxysm of periodic fever, there is great diversity in the intensity and duration of each paroxysm as well as of its several stages, as will be fully illustrated when the different forms of periodic fevers are treated of.

FEVER, CONTINUED. The division of fever which, according to the proposed arrangement, comes first under consideration, is the *continued*. This class of fevers has been so termed from the paroxysms consisting of remissions and exacerbations, without intervals of abatement or pyrexia, as in the intermittent and remittent types.

In systems of nosology, every variety of continued fever is comprehended under the term *Synochus* (from the Greek word συνέχω, to continue). The milder forms have been termed *synochus mitior*; the more intense, *synochus gravior*; the intensity depending on the various local inflammations which arise in the progress of the fever.

1. **SIMPLE FEVER.**—There is, perhaps, no disease in which the premonitory symptoms are so diversified as those of fever; this is owing to the general resemblance observed in the commencement of every febrile disturbance, whether idiopathic or sympto-

matic; and it is not until the symptoms have continued for some time, that the practitioner can discriminate the precise nature of the disease.

In idiopathic fever there is generally a period of undefined indisposition, evinced by disinclination to mental exertion: the individual is incapacitated from any ordinary mental effort, his perceptions are less clear and distinct than usual. To this condition of the mental powers the term *languor* is applied, and it is always an indication of the commencement of febrile action. A sensation of *lassitude* or diminution of muscular vigour is next felt; the patient feels fatigued and averse to any kind of exertion; if he attempt to walk, his movements are feebly or unsteadily executed. The muscles soon become unable to support the weight of the body; hence the recumbent posture is not only most easy, but indispensable. Boerhaave first applied the characteristic term *debilitas febrilis* to this state of the muscular system in fever. The alteration in the expression of the countenance, so marked in fever, is probably intimately associated with this condition of the muscular system, and forms a diagnostic of great value to the experienced practitioner, not only of the nature of the disease, but of the various changes which take place in its progress. It is difficult to give in words an idea of the febrile countenance: there is a look of anxiety, denoting much inward distress; the features are pale and sharp; and the whole expression is so changed as at once to alter the character of the countenance: hence the favourable impression which is always taken from any improvement in the aspect of the features.

Irregular chills and sometimes shivering come on; but more generally there are alternate fits of heat and cold of short duration, which continue to recur at intervals, even when the skin is hotter than natural; and it will be observed that during the time the patient complains of chilliness, the skin does not feel cold to another person, nor does the thermometer indicate any diminution of temperature. It appears, therefore, that the coldness is produced by some cause within the system itself, and is by no means to be attributed to external temperature, as it is observed in hot as well as in cold climates, and to recur when every precaution has been adopted with respect to the temperature of the apartment and the clothing of the patient.

About this period there is great restlessness, and uneasiness of an undefined and indescribable nature, which, after a short time, is succeeded by pain in the loins and extremities, with feeling of general soreness.

These symptoms, denoting the first stage of fever, are succeeded by those indicating reaction. The face becomes flushed, and the heat over the surface is steadily and uniformly above the natural temperature, varying from 100° to 105° Fahrenheit. The heat on some parts of the body is perceptibly greater than on others; hence, in those irregular accessions which take place, the increase is chiefly perceptible in the face,

hands, and feet. Sometimes, on the other hand, there is no increase of the animal heat in fever; the skin throughout the course of the disease retaining its natural temperature, or in some cases falling even below it: such deviations are always to be regarded as unfavourable, though, as physiology has not yet discovered the source of animal heat, we are ignorant of the causes on which they depend.

If the circulation be now examined, the pulse, which at the beginning is oppressed, will be found quick, seldom, however, exceeding 100. Besides increased frequency, it may have acquired other characters; it may be quick and soft, or full and strong, seldom, however, hard or tense. It occasionally, though very rarely, happens that the pulse does not, during the progress of fever, vary from its natural condition either as to frequency or power, and even when the other symptoms are well marked. A similar anomaly has just been pointed out as to the heat of skin, which now and then does not exceed, or even falls below the natural temperature.

Though the function of respiration is not necessarily involved in fever, still, when the febrile excitement is considerable, the breathing becomes hurried. This condition must be distinguished from that which depends on some inflammatory condition of the lungs. The absence of cough in the one instance, and its almost invariable presence in the other, with the sounds elicited by auscultation, will tend materially to aid the practitioner in forming a proper judgment of this symptom. It should also be kept in view that in those forms of fever in which the brain is severely affected, the breathing becomes embarrassed. It is sometimes short and quick, or slow and interrupted. In these cases the state of the breathing is the effect of the disturbance in the brain, and not of pulmonary disease.

When the fever has thus become developed, the primary disturbance of the brain is succeeded by symptoms which indicate increased action in the cerebral vessels. This is indicated by headach; the pain being in some instances confined to the forehead, sometimes to the occiput. It varies in intensity as well as duration, but is always increased on any movement of the body, or any circumstance which excites the circulation. In many instances of the mild forms of fever, however, the patient never experiences headach; he complains only of giddiness or of a sense of heaviness or weight, particularly in the occiput. It is not easy to explain the cause of these differences in sensation, but it is important to bear in mind, that they all depend on one and the same condition of the brain, and require similar though perhaps modified treatment.

As the disease proceeds, the languor and lassitude of the first stage give place to sensorial disturbance, indicated by great restlessness and irritability, and sometimes slight delirium towards evening, which abates or totally disappears in the morning.

The various senses are more or less disturbed: the hearing is often morbidly acute, so

that even slight sounds give uneasiness if not pain; sometimes it is dull and obtuse; the sense of smell is vitiated; the taste is so altered that common articles of diet are scarcely recognised, and there is generally great aversion or loathing of food; the mouth is clammy; the tongue covered with thin white fur; and there is more or less thirst.

The excretions are altered, both as to quantity and quality; the urine is high-coloured and turbid, or deposits a sediment on standing; and the evacuations from the bowels are generally of an unhealthy character.

The fever is now said to be fully formed, or, in popular language, to be at "its height." In the majority of cases, towards the evening, or in some instances at irregular intervals, there is an exacerbation, or general increase of the febrile excitement, which abates towards the morning. The accession is indicated by greater restlessness, by the skin becoming more hot, the face more flushed, and by increased thirst and frequency of pulse. It is probably in consequence of the increased velocity of the circulation through all the organs, and consequently in the brain, during these exacerbations, that the patient is so much more restless and indisposed to sleep; and hence it is that, when there is disposition to congestion or inflammation in any organ, it is often developed at these periods.

With regard to the duration of simple fever, the symptoms may continue without any particular change for a few days; but its limitation depends on a variety of circumstances. It may last only one day, and this constitutes the common *ephemeral* fever, which terminates in twenty-four hours; a form to which women in childbed, from a variety of causes, are occasionally subject: or it may go on for an uncertain number of days, or even weeks, terminating, however, in the majority of instances, about the end of the second or beginning of the third week. It not unfrequently happens that its duration is materially diminished by some spontaneous evacuation, either by the skin or bowels, or perhaps by some accidental hemorrhage; or without such spontaneous efforts of the system, by moderate venesection, if the febrile excitement require the loss of blood, or in milder cases, by purging, confinement to bed, and the adoption of a mild farinaceous diet.

The ancients, who accurately observed the phenomena and progress of fever, remarked that the symptoms shewed a tendency to abate at regular periods, which were called critical days. This crisis was observed to occur on the third, seventh, fourteenth, and twenty-first days from the commencement of the symptoms, or first invasion of the disease. If the symptoms passed over the first period, those who gave credence to this doctrine predicted, that the fever would go on to the second or beyond it; for example, if the symptoms did not abate on the seventh, that the fever would not terminate till the fourteenth day; if this day were exceeded, that it would run on to the twenty-first, and so on.

Modern physicians place very little confi-

dence in this restricted duration of fever. The ancients, being afraid of interfering in any way with the efforts of nature to get rid of what they supposed hurtful to the system, considered every kind of treatment improper, and were, therefore, more likely to observe, in the milder forms of fever, an abatement by crisis on particular days. The modern treatment of the disease, founded on more just views of its pathology or nature, is very likely to interrupt or disturb such regular periods of decline; and, therefore, though the doctrine of critical days is not in our day altogether exploded, practitioners are either less inclined to look for them, or to reject the idea as not according with nature. Besides, in fever complicated with local inflammation, such regularity in the crisis cannot be expected to occur; the symptoms, depending in some measure on the condition of the organ, which may, in the progress of the disease, have become inflamed. It cannot, however, be doubted that the notion of critical days was originally founded on correct observation, that fevers are disposed to terminate favourably or unfavourably at certain periods; and though such critical termination cannot in every, or even in the majority of instances, be discerned or traced, the fact, that simple or uncomplicated cases occasionally do so, should always be kept in view.

The convalescence, or period of the decline of fever is observed to be gradual; the feelings of the patient improve, his countenance becomes animated, and its expression so altered, that except by those who are acquainted with the previous aspect of the countenance, the individual would not be recognised—the sleep becomes longer and more refreshing—the pulse comes down gradually till it returns to its natural frequency—the skin becomes cool—the tongue clean—the appetite for food returns—the thirst ceases, and the strength and spirits improve. These favourable changes indicate the stage of convalescence, which is confirmed in a few days under proper management, especially if great attention be paid to the regulation of diet, and avoiding undue bodily or mental fatigue. No consideration should induce the practitioner to relax in his close attendance during this most important, but too often neglected period of the disease.

The description now given applies to the mild epidemic fever of this and other temperate climates. It is almost unnecessary to state, that there is every gradation not only in the intensity, but in the duration of the symptoms. The symptoms may be so mild as scarcely to require more than an aperient, quietude, and abstinence; or they may assume a severe character,—the fever passing into some of the other forms to be afterwards described.

Inflammatory fever.—A variety of continued fever of a hyper-acute form is occasionally observed, and though not very common in temperate climates, it does now and then occur, and requires notice. It has been called inflammatory fever (*synocha*), and may occur at all ages and in all habits, forming the general character of fever in young and plethoric sub-

jects, who have great muscular power and corresponding vigorous circulation. When it occurs in cold and temperate countries, it is distinguished from simple fever (synochus) by its more sudden invasion,—by the more pungent heat of the skin, flushing of the face, suffusion of the eyes and intolerance of light—more intense headach, throbbing of the carotid and temporal arteries, watchfulness, and delirium. The pulse is seldom very rapid at first, but as the disease proceeds, it becomes full, round, and tense, but never remarkably frequent, and the blood after venesection generally exhibits the puffy coat. The breathing is quick, the thirst incessant, and the febrile restlessness distressing. In some instances, there is nausea and vomiting, with pain in the epigastrium, stretching to either hypochondrium; more especially if this form occur in the summer and autumn months in warm climates, where it is generally termed bilious or bilious inflammatory fever. When inflammatory fever becomes fully developed, spontaneous hemorrhage not unfrequently occurs; if it proceed from the nose, it generally affords great relief to the symptoms, on which account it should not be interfered with, unless it produces feelings of exhaustion.

From the violence of the general excitement in inflammatory fever, local inflammations are exceedingly apt to supervene. It may also pass into other forms: we accordingly find that in warm climates, more especially in the West Indies and some districts of the United States, it assumes very often the remittent type, or it may lapse into a low kind of typhoid fever.

Its duration varies according to circumstances. It now and then assumes an ephemeral character,—disappearing in twenty-four hours: mild cases of longer duration by proper management may pass off in a few days; but if the symptoms be neglected in the commencement, the fever may last two or three weeks or longer, and then gradually subside, the symptoms losing their acute character as the disease advances.

It is proper, however, to state that in our experience of the epidemic fever of this country, this form, (synocha,) if it really do occur, has been seldom observed. A few sporadic cases, which have many of the essential characters detailed, certainly present themselves occasionally in the spring months; but these form a comparatively small average proportion of the ordinary fever of Britain. It is, therefore, to the fevers which occur in warm climates that the description given more particularly applies; the character of fever, as will be afterwards explained, being materially influenced by climate and season. It is also necessary to bear in mind the local inflammations which almost invariably arise in the course of these acute fevers, and the effect of such complications on the febrile symptoms.

Gastric fever.—When the symptoms of common fever are attended with more than ordinary gastric derangement, the term *gastric fever* has been applied. Hippocrates, with his characteristic discernment, evidently alludes to this variety of fever, in treating

of acute diseases with heat and biliary dejections; and Galen, the first writer who distinguished fevers into sanguineous and bilious, founded his idea of the latter from the condition of the stools. This form of fever has in later times been called by different names. Baillou first termed it *gastric fever*; Hoffmann, the *choleric*; Baglivi, the *mesenteric*; John Peter Frank, *febris continua gastrica*; Pinel, the *meningo-gastric*.

Disorder in the alimentary canal gives rise, not unfrequently, to fever of a particular form. In other instances, symptoms of gastric disorder may supervene on common fever: in either case, the train of symptoms, which are very much alike, and require a similar mode of treatment, are, in the one case the cause, in the other, an accidental accompaniment of the fever.

Gastric fever may occur sporadically; at other times the gastric symptoms form the prominent type of an epidemic; and from its prevailing in the summer and autumn months after very hot weather, it would seem to be produced by some atmospheric or terrestrial emanations peculiar to this season of the year. There are several accounts on record of epidemic gastric fever: indeed, the fevers of Britain towards the end of summer and in the autumn, are almost uniformly accompanied with gastric irritation, and from our individual experience of the character of fever for the two preceding years (1830 and 1831,) we can affirm, that an unusual degree of gastric disorder has accompanied the disease during the whole of that period. The type of the fever has moreover been low and typhoid to a degree which has not been witnessed for many years preceding, so much so as to preclude the employment of evacuations of any kind, and to render stimuli necessary to an extent very unusual in the London Fever Hospital.

From a communication with which we were lately favoured by our friend Dr. Brown of Sunderland, it appears that a similar type of fever preceded the late visitation of cholera in the north of England. This fact, with the similarity of the symptoms of epidemic fever in those situations in which cholera has hitherto appeared, renders it probable that some peculiar condition of the atmosphere has given a tendency to gastric disorder, not only in fever but in other acute diseases. It is a singular circumstance, also, that when cholera appeared in London, epidemic fever sensibly diminished both in frequency and severity, while the gastric irritation and prostration of strength, which formed the prominent features of fever, have also nearly subsided.

In gastric fever there is great variety in the mode of attack and sufferings of the patient. In some cases there is so little evidence of illness that the patient follows his ordinary pursuits, thinking he is only indisposed from derangement of stomach, till the prostration of strength and the gradual accession of febrile symptoms, shew evidently the nature of the disease. In other cases the sym-

ptoms from the beginning are so well marked, as to leave little doubt of their nature and tendency.

The precursory symptoms are very similar to those of other forms of fever—sense of chilliness, rigors, irregular flushes of heat, languor, lassitude, pain in the head, loins, and extremities. The face is pale and sallow, the conjunctiva yellow; the mouth clammy and bitter, the breath fetid; the tongue at first is slightly coated with thin white or grey fur, which increases in thickness, becoming yellow over the body and root, while the point and edges are red: in other cases, it is clean and morbidly red from the beginning.

More or less disturbance of the stomach is observed early in the disease; there is pain or sense of weight or distension in the epigastrium; often nausea and retching, which generally ends in vomiting of bilious fluid: the state of bowels is variable; there is either constipation alternating with diarrhoea, or there is purging from the commencement, the stools being watery, of a pale green or brownish yellow colour, extremely fetid, and occasionally mixed with blood. The pulse, which from the commencement may not have been much accelerated, now becomes rapid; the breathing hurried; the heat of skin pungent; the febrile uneasiness and general pain increased; and towards evening, there is exacerbation of the symptoms, with watchfulness and delirium. As the morning advances, however, a distinct remission takes place, accompanied with gentle moisture on the forehead and chest. The coating on the tongue becomes more thick, sometimes dry and brown; and the urine, scanty and passed with pain, deposits a lateritious sediment.

At a still more advanced period of the disease, we observe the morning remissions so slight as to be scarcely noticed, while the whole complexion of the symptoms becomes aggravated; the delirium, which was perhaps only noticed towards evening, is constant; the tongue, palate, and throat are more dry, and covered with viscid mucus, or a dry, hard, black crust envelopes the tongue, which is sometimes irregularly fissured and covered with aphthæ; the speech and sense of hearing are impaired; the eyes suffused; the pulse is very rapid and compressible; the evacuations are passed unconsciously, with tympanitic distension of the abdomen. This congreagation of symptoms denotes an intense and advanced form of gastric fever, from which the patient not unusually perishes, though if the previous powers have been vigorous, and the treatment judicious, the patient may be recovered. When a favourable termination is about to take place, the delirium abates, the morning remissions become again distinct and of longer duration, the skin cool and soft, the tongue and palate moist, the former throwing off its dark incrustation and exhibiting the subjacent mucous membrane morbidly red and tender; the bowels become pungent, the stools more consistent, and the abdomen feels soft from the subsidence of the tympanitic distension.

When a fatal termination is about to ensue, the yellowness of the eyes, headach, delirium, and flushing increase; the patient, at one time furious, becomes drowsy and comatose; the stools, and occasionally the urine, bloody and passed involuntarily; the tongue, tremulous, and, as well as the teeth, covered with dry black fur, cannot be protruded. To these symptoms succeed picking of the bed-clothes, starting of the tendons, hiccup, rapid breathing, cadaverous smell of the perspiration and breath, cold sweats, imperceptible pulse, and coldness of the extremities.

It is necessary to state that in gastric, as well as other forms of fever, local inflammations arise in its progress. It is, therefore, important to watch the symptoms in the different organs, more particularly the brain, which from the inflammatory type of the fever at the commencement is often severely affected. In like manner the several organs in the chest and abdomen may become inflamed, and render the disease formidable.

Frank states that in some cases, quantities of worms are expelled from the stomach and bowels during gastric fever. In such instances the febrile symptoms are accompanied with those peculiar to vermination—wandering pains, itching of the nose and anus, prominence of the abdomen, vomiting, tenesmus and copious mucous stools.

The duration of gastric fever is uncertain. When the disease is mild, it may not last above a week or ten days; generally, however, it is tedious and protracted, more especially if neglected in the early stage. It is unnecessary to state that its duration will be materially affected by any inflammatory complication with which it may happen to be associated.

The history of epidemic gastric fever, written for this work by Dr. Cheyne, gives an admirable sketch of this variety of fever; and we beg particularly to call attention to the observations of that able physician on this subject. (See FEVER, EPIDEMIC GASTRIC.)

2. COMPLICATED FEVER.—In the preceding observations it has been our object to shew that in *simple* fever the disturbance in the various organs, however severe, is only functional, no inflammation in any organ having as yet taken place.

It is necessary, however, that the practitioner should bear in mind, that although fever at its commencement may be mild, in a large proportion of cases it assumes a severe character, in consequence of some local inflammation arising in its progress. Hence, whatever be the primary effect of the exciting causes on the various organs, the transition from excitement to inflammation is often rapid, more especially when there is predisposition to disease in any particular organ.

From what has been previously advanced, as well as from the facts which will be adduced when the causes of fever are discussed, there are strong grounds for supposing that the febrile poison produces a peculiar or specific effect on certain organs of the body in the first instance. The affection thus pri-

marily induced, whatever it may be, is not, however, of an inflammatory character, though it is evident, both from symptoms observed during life, and from morbid appearances after death, that inflammation does arise in certain organs in the progress of fever. If the febrile poison be not in a state of great concentration, it may be presumed that a peculiar action only is exerted on one or more organs; if the poison be in a state of greater activity, it would appear to produce severe organic lesion—inflammation, and its consequences.

We do not pretend to explain the *modus operandi*, or theory of action of the causes alluded to; or why, in individuals exposed to the same causes, in one case very slight effects, while in another the most severe and often fatal symptoms are produced. There may be greater aptitude for the reception of the febrile poison in one person than in another, arising from individual peculiarity or idiosyncrasy, as it has been termed.

This tendency of the primary febrile affection to pass into inflammation, which local inflammation is the cause of the severity in the majority of cases of fever, should never be overlooked. It is equally important to bear in mind that the inflammatory action which supervenes, is of a less intense kind than in the ordinary phlegmasiæ.

There are few organs in the body which are not occasionally affected in fever. Some, however, suffer more uniform and severe lesion than others; as for instance, the brain and spinal marrow, the mucous membrane of the lungs, and of the alimentary canal. Inflammation of the parenchyma of organs is occasionally, though less frequently, observed.

Cerebral complication.—From the almost invariable disturbance in the brain and nervous system in fever, it is particularly necessary to watch any tendency to transition from functional disorder to inflammation of the brain. Not only the symptoms during life, but the morbid appearances discovered after death prove that inflammation of the membranes of the brain is by far the most frequent and dangerous of the local inflammations that occur in the progress of fever.

The cerebral affection assumes various degrees of intensity. In some cases it is mild, in others severe; and between these extremes there is every intermediate modification. Sometimes the cerebral affection appears in solitary instances during a mild epidemic, or it may form the prominent character of epidemic fever.

If the symptoms be attended to, it is impossible to overlook the first indications of acute affection of the brain in fever. The general symptoms may at first be little urgent, and proceed as has been stated in the history of mild fever. The patient, however, is afterwards observed to complain of more constant and severe pain in the head, accompanied with throbbing of the carotid and temporal arteries, flushing of the face, and heat of the scalp. In general the pain is confined to a particular part, very often to the forehead and temples,

occasionally shooting to the occiput: at other times it is felt chiefly in the back of the head.

In many instances the cerebral inflammation is not indicated by pain, but by giddiness. Even if the head be shaken, or suddenly moved, no pain is induced, though the giddiness and flushing are increased. Moreover, when pain in the head has existed, it is often of short duration; but, notwithstanding it has ceased, the local affection may be proceeding with equal, if not increased vigour, and, if not arrested, may speedily destroy life. The absence of pain in such cases, therefore, must not be allowed to throw the practitioner off his guard; he must be guided in his opinion of the condition of the brain by the presence of other equally pathognomonic signs. Thus the eyes are brilliant or suffused, their expression either morbidly animated or dull, but generally sensible to light; hence the contracted eyebrows, half-closed eyelids, and the relief experienced from a dark room.

The sense of hearing is also morbidly acute. Sounds which the patient has been accustomed to hear without even exciting attention, become disagreeable, or even painful; every precaution in such cases is therefore taken to lessen the intensity of sounds.

Though the febrile action usually produces a state of watchfulness, this condition is much increased when the brain becomes inflamed; it is often accompanied with a degree of restlessness or moaning; but after the cerebral vessels have been unloaded, the patient generally becomes tranquil, and enjoys intervals of refreshing sleep.

There is also in cerebral inflammation more or less intellectual disorder. In milder cases, the patient is perfectly conscious while awake, but if he drop asleep, it is interrupted by talking; and when he awakes, he is for a time forgetful, utters perhaps a few incoherent sentences, and then becomes perfectly sensible. As the evening approaches, however, the confusion becomes again perceptible, especially on the termination of the occasional short periods of disturbed sleep which attend this stage of the disease. In more severe cases, delirium is observed at intervals during the day when the patient is awake; and if the symptoms in the brain be urgent, it is incessant, loud, and noisy.

The symptoms enumerated indicate a degree of inflammation of the brain, not uncommon in the epidemic fever of this country, which, if treated by the early and vigorous employment of suitable measures, is in general readily subdued, and the recovery proceeds satisfactorily.

The cerebral affection, however, occasionally assumes a more severe form; and those destructive changes which often rapidly take place in the delicate organization of the brain, sufficiently shew the intensity of the previous inflammatory action. The symptoms which indicate this more severe form of brain affection differ from those which attend the sub-acute, chiefly in degree. The pain is more severe and constant; the patient often rolls the head

from side to side; the eyes are more suffused; the sensibility to light and sound is greater; the breathing is rapid and suspirious; the anxiety of countenance is increased; the restlessness and delirium assume a more formidable character: while the noisy vociferation or screaming is incessant, the violence of the patient often requiring restraint. The pulse is more round and tense, but in some cases it is soft, irregular, or intermitting. The skin is hot, and often perspires profusely, in consequence of the incessant bodily agitation or struggling. If active treatment be neglected in the beginning, or should the attack in the brain be of such a severe character as to bid defiance to the treatment employed, the powers of the system give way, the delirium does not subside, but it loses by degrees its acute character; the patient becomes drowsy, and observant only when roused; the eyelids are half closed; sometimes there is squinting or rolling of the eyeball, with dilatation of the pupils; muscular tremor and starting of the tendons come on; deglutition is performed with difficulty; and the drowsiness finally passes into profound coma. The patient then becomes insensible to all external objects; the urine and stools are passed involuntarily; the tongue becomes dry and brown; the teeth and lips covered with sordes; the pulse rapid and feeble, occasionally irregular; and life is speedily destroyed.

It is necessary to bear in mind that between acute and subacute inflammation of the brain in fever, there is every variety of degree or intensity. In many instances the cerebral inflammation assumes a slow insidious character, and is only detected by vigilant examination. Sometimes when there is considerable excitement in the brain, the pulse and other febrile symptoms do not indicate much febrile action; the pulse may not be above the average frequency of health. In some cases the pain ceases entirely, and is succeeded by partial insensibility. The skin may be cool, and the tongue little furred; yet notwithstanding these favourable circumstances, a low form of chronic cerebral inflammation may be going on.

In some instances, again, inflammation of the brain suddenly comes on in the progress of the fever, when there were no previous warnings of its approach. Hence the necessity of watching with incessant vigilance every case of fever during its progress; as no case, however mild or promising, is free from the possibility of sudden attacks of inflammation of the brain.

Pulmonary complication.—The organs of respiration at certain seasons, and in particular epidemics, suffer from inflammation in the course of fever. Laennec states on this subject, that "one of the most interesting results which auscultation has furnished is the constant presence of a catarrhal affection, either latent or manifest during the whole course of continued fever. At the commencement, and most commonly through the whole period of the fever, the catarrh is latent, without cough and expectoration, and only to be discovered by the ste-

thoscope. Sometimes it becomes manifest on the approach of a crisis; and, indeed, the crisis by expectoration noticed by the ancients is neither more nor less than this catarrh. Catarrhal fever is applied to those forms in which the catarrh, just stated to be inseparable from continued fevers, early manifests itself, and gives rise to a copious mucous expectoration. The same appellation has also been given to those violent catarrhs which are accompanied by a symptomatic fever; but in this case the fever, though considerable at first, and often of long continuance, soon loses the character of acute fevers, terminates long before the catarrhal affection, and never presents that combination of cerebral congestions and abdominal disorder, more or less severe, exhibited by true idiopathic fevers, which must be considered as diseases affecting at the same time a great many organs, and perhaps still more particularly the fluids. In eruptive fevers the pulmonary catarrh is equally constant, and most commonly in them it is manifest. In measles it is well known always to be so, and it continues often for a long time after this disorder is cured. The same thing occasionally takes place after simple continued fevers; but in these I have also had frequent occasion to observe, that when a crisis takes place, at the very time when the lateritious sediment shews itself in the urine, every sign (even stethoscopic) of perhaps a very intense and extended catarrh disappears at once with the coma, tympanitic affection, quick pulse, heat, and earthy character of the skin. During the paroxysms of intermittent fever the stethoscope detects in like manner symptoms of catarrh, for the most part dry and latent, and of which some traces remain in the intervals. Even the fevers which are most decidedly symptomatic, for instance those arising from a wound, very commonly present the same phenomena. It would, therefore, seem that the first effect of febrile action is to produce a congestion in the mucous membrane of the bronchi; and this effect is readily conceived on taking into consideration the energy of the actions of concentration and expansion which constitute fever. The inflammatory fever of nosologists, that is, the fever characterised by a flushed countenance, moist and clean tongue, and a moist and moderately hot skin, is, of all fevers, that in which the marks of dry catarrh are the least perceptible. I have even observed two cases of this fever in which the sound of respiration through their whole course was uniformly strong and *pure*, that is, unmingled with any kind of rattle over the whole extent of the lungs. It may here be remarked that this species of fever is, of all, the least liable to change into another form; that it is rarely accompanied by symptoms of any considerable degree of cerebral congestion; that it is hardly ever attended by signs of irritation, or by eruptions or ulcerations of the mucous membrane of the intestines, or by a tympanitic state of the same; and, lastly, that it is almost the only fever in which the blood exhibits the inflammatory crust. In all these respects, then, the inflammatory fever appears

to differ either in its nature or cause from other continued fevers; it is unquestionably the most simple of all, and can least of all be considered as a primary affection of the solids. Pulmonary catarrh is occasionally a striking symptom of pernicious intermittent fever. This appears to have been the case in the epidemic catarrhal fever of 1778; for we find a French Medical Society about that time giving it as a prize question, '*To ascertain the relations of remittent catarrhal and pernicious fevers.*'" (Laennec, p. 101-2.)

Although bronchitis is a very frequent complication of fever, especially in some epidemics, and at particular seasons, it is by no means so universal as the observations of Laennec would lead us to suppose: neither is it to be considered an essential constituent of either continued or remittent fevers; but that it does occasionally supervene in both forms is undoubtedly true. It is perhaps, of all the complications, the most universal in the fever which occurs in the winter and spring months in this country; and no doubt its frequency is in a great measure to be imputed to the sudden variations of temperature peculiar to the climate of Britain.

The symptomatic bronchitis of fever is scarcely to be recognised during the first few days. When it becomes more developed, the symptoms are, besides those which are proper to fever, pain or constriction in the chest, slight acceleration in the breathing, with wheezing sound (mucous rattle) of the respiration on applying the ear or stethoscope to the chest. There is generally at the same time cough, which comes on in fits; it is dry in the early stage, but in the course of a day or two expectoration of viscid mucus, which is expelled with difficulty, and occasionally streaked with blood, takes place. As the bronchitis proceeds, the expectoration becomes more copious and easy, and of a pale yellow or greenish colour. The mucous rattle may be partial or extensive, according as the bronchitis is confined to a small or large portion of the lung. When it is heard over the whole of one lung, the bronchial affection is severe; if it be distinct in both lungs, the case generally terminates fatally. In some cases, however, there is no cough, the existence of the bronchial affection being indicated by slight acceleration in the breathing, with sense of constriction in the chest. The absence of cough renders the local disease very apt to be overlooked; but the state of the respiration, with the aid of stethoscopic examination, will generally sufficiently point out its existence.

In many instances, especially in persons who have had former attacks of pulmonary catarrh, the bronchial affection assumes a more intense form. The breathing is hurried and oppressed, especially after fits of coughing; sometimes it is slow, laborious, and wheezing; the lips are of a dark blue, or livid colour; the cheeks flushed, or of a dusky hue. In still more intense cases, the whole countenance becomes suffused with dark-coloured blood, and from the air-cells being clogged with viscid mucus, the blood

is not duly arterialised; the functions of the brain are, consequently, more or less embarrassed, according to the severity of the bronchial affection. The patient first becomes occasionally incoherent, and afterwards comatose; the pulse soft and feeble; the tongue covered with deep brown, or almost black crust, while the temperature of the skin, more especially of the parts at a distance from the centre of the circulation, falls below the natural standard. It is unnecessary to add that these symptoms indicate great danger; for although recovery under such circumstances may take place, the majority die from the destructive effect of unoxxygenated blood on the brain and nervous system.

It should be kept in mind, that in cases of fever accompanied with severe affection of the brain, the various local complications become so much obscured as to be in many instances entirely overlooked. It has been already remarked that symptomatic bronchitis is often latent in the early stage. When the affection of the brain has been urgent, the bronchial affection never becomes so fully developed as to be recognised by its usual symptoms; it may be going on in an intense form, without any suspicion of its existence. The advantages to be derived from auscultation under such circumstances must be evident; and, therefore, in all the severe forms of fever, the application of the stethoscope should never be omitted.

Though bronchial inflammation is the only form of disease in the chest which can be said to be peculiar to the severe forms of fever, yet true pneumonia and even pleurisy may arise in the progress of the fever, more especially during the stage of convalescence in cold, variable weather, and often under such circumstances prove fatal.

In some instances these inflammations, also, assume a slow insidious character, or become entirely latent; and so obscure do such complications become, that extensive organic changes have been discovered after death, the signs of which have been either very doubtful or entirely wanting during life. Such cases are more common when the previous affection of the brain has been severe; and hence the necessity of frequent stethoscopic examinations in the course of fever, especially if protracted.

It is here necessary to advert to a particular form of fever, which has at various times appeared epidemically in different parts of the globe. From the catarrhal symptoms which gave the peculiar character to the disease, it was termed *catarrhal fever*, *epidemic catarrh*, or *influenza*. The disease appears to have been the consequence of an atmospheric poison acting on the mucous membrane of the air passages; and from the extent to which it prevailed, and other circumstances observed in those who were seized with the disorder, to have had strictly and truly an epidemic origin. It spread over large territories, travelling from north to south, though less frequently, from east to west. The epidemic of 1781-2 is recorded to have first made its appearance in China, and to have traversed Asia

into Europe; from thence it crossed the Atlantic, and extended the following year over the continent of America.

The symptoms usually commenced with alternate fits of chilliness and heat; sometimes shivering preceded the febrile indisposition. The patient soon after felt great languor and feebleness; the debility and depression of spirits being always to a greater degree than could have been anticipated from the mildness of the other symptoms. The most striking feature of the disease next appeared—a distressing pain and sense of constriction in the forehead and temples, often extending over the whole face, and accompanied with a sense of soreness in the cheek-bones. These symptoms were followed by uneasy sensation about the eyes, sneezing and hoarseness, incessant cough, with soreness and constriction about the præcordia, or stitches in the chest, and pain in the back and loins. To these succeeded lachrymation and profuse discharge of thin mucus from the nostrils and lungs, which continued through the course of the disease.

The appetite and sense of taste were much impaired or entirely lost; in many cases there was nausea, and sometimes vomiting; the tongue being coated with thin mucus. The thirst was inconsiderable; the state of the bowels variable; in some they were regular, and in others confined; sometimes there was spontaneous diarrhœa, generally attended with pain, at various periods of the disease.

The pulse, though frequent, was soft and easily compressed; the heat of skin was relieved by irregular sweatings. Daily exacerbations and remissions of the cough and fever were in many instances observed; in others, they did not occur, or if they did, were so slight as to escape observation.

The disease was in some cases very mild; sometimes there was only slight fever, with soreness of the throat and uneasiness in the chest, but no discharge of mucus; but the languor and lassitude were always well marked. In some the disorder began like smart fever, and in a day or two assumed the characters of the common cold, and continued to hang about the patient for a period varying from a week to a month.

Abdominal complication.—Of the organs situated in the cavity of the abdomen, the mucous membrane, but more especially the follicles of the small intestines, undergo certain changes, and although these intestinal lesions are by no means invariable, yet, as we have before stated, in some epidemics, and in the fever of particular localities, they are frequently observed, and form severe and often dangerous complications.

In milder cases of the common fever of this country there is probably little if any intestinal affection; but in the more severe forms the intestinal disease becomes a prominent characteristic of the fever, and generally induces sympathetic disturbance of the brain, or should the cerebral affection have already existed, never fails to increase it. In gastric fever the abdo-

mal symptoms are often so obscure and insidious as scarcely to attract serious attention till the disease has made some progress. Indeed, in fever, destructive disorganization of the bowels may be going on without the practitioner or patient being at all aware of its extent, from the want of diagnostic symptoms to indicate the intestinal lesion on which the danger depends. It is often the cause of slow and protracted fever, and a febrile indisposition which is mild at the beginning often becomes serious from the supervention of this secondary intestinal affection. It may be suspected in such cases, when, in addition to the ordinary febrile symptoms, the skin is dry and parched, the thirst excessive, the lips and prolabium red, the tongue red at the point and margin, the bowels irregular (diarrhœa alternating with constipation), and the abdomen tympanitic, with or without tenderness.

When the brain becomes sympathetically disturbed, the face is flushed, delirium supervenes, followed by more or less stupor or coma, and insensibility to pain and to the evacuations by urine and stool.

Dr. Bright, who has given an excellent account of the symptoms and morbid anatomy of this intestinal affection as it occurs in the course of continued fever,* considers diarrhœa to be the first symptom which indicates its existence. This sometimes exists from the beginning, but more commonly does not come on for nearly a week; the stools are frequent, five, six, or eight in the course of twenty-four hours, and, at first, feculent, dark, and fetid; but afterwards thin and watery, and as if ochre had been mixed with them. The ochre diarrhœa Dr. Bright considers to be characteristic of the commencement of intestinal ulceration, the increasing or decreasing frequency, quantity, and consistence of the evacuations indicating the progress of the intestinal disease. There may or may not be abdominal tenderness or tormina, but when there is pain of the abdomen on pressure, he considers it indicative of inflammation having extended to the peritoneum. Dr. Bright corroborates the opinion already given as to the subsequent sympathetic disturbance of the brain arising from the condition of the intestines, but admits that the cerebral affection may precede and be entirely independent of the intestinal disease, though it progressively increases or diminishes according to the progress of the ulceration of the bowels.

We have already alluded to the opinion entertained by many French pathologists that the follicular disease which was first described by M. Petit is the primary cause of fever. Cruveilhier states that, after he and his fellow-students had watched at the Hôtel Dieu the progress of severe fevers (*les fièvres graves*), and the seat and character of the lesions after death, they became tired of the vague denomination of inflammatory, bilious, mucous, adynamic, and ataxic fevers, finding the same anatomical cha-

* Report of Medical Cases.

racters were always discovered in the intestines; they therefore proposed to substitute the term *intestinal fevers*, for the more vague phraseology which had been introduced. He asserts that this follicular disease occurs under three forms: 1. the acute or inflammatory form; 2. that accompanied with prostration and stupor (*adynamic form*); 3. that attended with cerebral excitement and delirium (*utaxic form*). Inflammatory complications may arise and give a particular character to the disease, but still the original primitive follicular disease exists, and constitutes the most characteristic feature of the malady, which is seated always in the extremity of the small intestines. The ileo-cæcal valve is the principal seat of the lesion; it extends thence as from a centre, gradually diminishing from the last twelve inches to two or three feet in the ileum.

The follicles of the cæcum, appendix cæci, and ascending colon, are also occasionally affected. The mesenteric glands corresponding to the diseased portion of intestine are inflamed and enlarged: hence the name *entero-mesenteric* fever given to this disease, of the symptoms of which Petit has given the following summary:—Feeling of debility and general indisposition; loss of appetite; lassitude; and irregular attacks of fever; the countenance expressive of prostration; the skin, especially about the lips and *alæ nasi*, often harsh and dry; disinclination to exertion; great torpor and intellectual dullness. The febrile symptoms are obscure during the day; but there is an exacerbation towards night, without shivering or much heat of skin; the eyes, before languid, become injected; there is slight delirium; the thirst is urgent; the teeth are dry; the tongue is coated with grey fur; the stools, which vary in frequency and abundance, are bilious, or serous, and insufficient to account for the prostration; the abdomen is soft, and not distended; there is little if any tenderness, but pressure applied to the right side, between the umbilicus and crest of the ileum, often causes pain. As the symptoms increase, the cheeks become livid; the eyes sunk and suffused; with constant somnolence and delirium, though the patient when roused gives intelligent answers. *Petechiæ*, subsultus, and tremors supervene; the pulse becomes rapid and compressible; the teeth covered with sordes, and the tongue with brown or black crust. Abdominal tenderness now succeeds, the pain being in some cases still confined to the ileac region, and without tympanitis; in other cases more diffused, and accompanied with distention. The stools are frequent, serous, and offensive, and the urine is scanty. Excoriations succeeded by sloughing of the nates, and tendency to gangrene on those situations to which blisters have been applied, protract the sufferings of the patient, unless, as generally happens, death puts an end to complicated misery. It is asserted by the French pathologists that it is the most common form of fever in France, and that it may occur sporadically, or constitute the principal feature of epidemic fever.

The successive changes which take place in the mucous follicles during the progress of fever will be explained in the morbid anatomy. It will then be shewn that the destructive processes of ulceration go on progressively, until the coats of the intestines are destroyed in succession, and intestinal perforation at length takes place. The symptoms which denote that this lesion has occurred are, sudden intense pain, with rapid distention of the abdomen, small quick wiry pulse, and peculiar alteration in the countenance. Intestinal perforation is always fatal, generally within thirty-six hours.

Though *peritonitis* cannot strictly be said to form one of the complications of fever, it occasionally supervenes, more particularly at the period of convalescence. Peritoneal inflammation is readily distinguished by the acute pain in the abdomen, increased on pressure; by the knees being drawn up towards the belly; by the sickness or vomiting, and the small wiry incompressible pulse. In some cases, however, there is neither sickness, vomiting, nor frequency of pulse; but only tenderness of the abdomen on pressure. Whether, therefore, this symptom (abdominal tenderness) be accompanied with other distinguishing signs of the disease or not, it should never be overlooked, but treated with decision, as abdominal inflammation may be going on, and even proceeding to a fatal termination, with a quiet pulse and soft skin.

In the preceding account of the complications which occasionally arise in the progress of fever, we have confined the description to cases in which the lesion has arisen either in the brain, in the chest, or in the abdomen.

It happens, however, that in some instances complications take place in more than one organ at the same time. Thus there may be cerebral affection from the commencement of the fever, and in its progress pulmonary or abdominal symptoms may arise; or there may be primary gastric symptoms, with which the brain sooner or later sympathizes. In still more severe cases, inflammatory symptoms in the brain, chest, and abdomen may exist at the same time. It is seldom, however, that in such instances the organs suffer equally, there being generally one on which the inflammatory action has seized with greater intensity.

It is important to remember what has been already stated, that in those more severe cases in which the cerebral affection predominates, should inflammation in some other organ subsequently arise, the symptoms are more or less masked by the cerebral disease. Hence arises the obscurity of the symptoms in those cases of latent pulmonary disease with which fever is frequently complicated, the symptoms being in a great measure concealed by the condition of the nervous system.

In like manner, should peritonitis supervene, the pain may be so slight as not to be felt even on pressing the abdomen; if, however, this condition of the brain subside, the tenderness of the belly becomes developed,

so that the practitioner is very apt, if not aware of the cause of the sudden sensation of pain, to ascribe it to an unexpected attack of intestinal inflammation.*

3. TYPHUS FEVER.—Different explanations have been given of the origin of the application of this term to a peculiar form or type of fever, characterized by the more early and severe affection of the brain and nervous system—by the more constant changes which the mucous membranes undergo—by affection of the cutaneous and glandular systems—and in the advanced stage by great prostration and symptoms denoting putrescence.

According to some it is derived from the Greek word *τύφος*, signifying *stupor*; and by those it is affirmed, that the peculiar expression of stupor in the countenance first suggested its application. By others it is contended that the term is deduced from *τύφος*, to smoulder, or to burn and smoke without vent.

Various other appellations have been given to this class of fevers. It has been designated *malignant fever* from the severity of the symptoms. Willis termed it *nervous fever*; Huxham the *slow nervous fever*. John Peter Frank combined, under the name *nervous*, every fever accompanied with prostration and unusual affection of the nervous system; other writers have termed it *prison, jail, hospital, camp fever*, &c.

The order first established by Pinel, to which he gave the name *adynamic*, (want of power,) is more closely allied to typhus than any other type of fever. It is occasionally observed during the prevalence of epidemic fever, and distinguished by great debility, prostration, feeble but not always accelerated pulse, intellectual disorder, impeded or difficult articulation, and involuntary evacuation of the urine and stools.

A variety of this form he called *ataxic* (irregular): it resembles the *adynamic* as to its origin, but he conceived there was greater disturbance of the nervous system, generally the effect of subacute cerebral inflammation.

We have been able, during the prevalence of epidemic fever, to discriminate both the *adynamic* and *ataxic* varieties, and we were certainly struck with the accuracy of Pinel's description; but though these forms bear a strong analogy to typhus, we think they only form an intermediate class between the more acute and typhoid types.

Though the majority of French writers have retained typhus fever in their arrangement as a distinct class, others, more especially Louis and Cruveilhier, as we formerly stated, ascribe the whole symptoms to primary affection of the mucous follicles of the intestines.

To this, however, we by no means assent, as we have traced the progress of typhous fever, both in the London Fever Hospital and in private practice, to its fatal termination, and on the most minute examination have been unable to discover the follicular disease which these authors state to be so invariably its cause; while on the other hand, we have met with follicular ulceration in individuals the symptoms of whose previous disease had no resemblance to those of typhous fever.

The typhoid form of fever is observed in some individuals during an epidemic of a very different type. When such sporadic cases occur, they probably arise from some peculiarity in the individual, or in the circumstances in which he may be placed. It is not uncommon to find fever, which at first is very mild, assume by degrees the typhoid character. If an individual, seized with fever, reside in an unhealthy district, or be confined in a small crowded apartment, where no attention is paid to ventilation and cleanliness, the probability is that a disease, comparatively mild at first, will be converted into one of severity and danger, from the low character which the symptoms assume.

This is corroborated by the amelioration in the general aspect of the case within a short time after a patient has been removed to a more open district, or into a well ventilated chamber. Physicians attached to fever hospitals are often struck with the marked improvement under such circumstances. The amelioration is not to be imputed to the treatment pursued so much as to the effect of a more pure atmosphere and the frequent ablution and changes of linen, which are so essential in fever.

At other times the type of an entire epidemic is typhoid, and of such epidemics there are many recorded histories; hence the importance of endeavouring to ascertain, after the example of Sydenham, not only the character of fever in different localities, but the nature of the epidemic at different seasons, that the physician may successfully apply those principles of treatment which the type of the fever requires.

There can be no doubt of the existence of every intermediate gradation between the common forms of fever (*synochus*) and typhus, so that it often becomes a matter of nicety to discriminate to which class a particular case or number of cases properly belongs. Sometimes we find, indeed, the one form passing into the other, more frequently mild fever lapsing into typhus.

There is, in general, a perceptible difference in the severity of the symptoms in different cases of typhus. This has led to the distinction, proposed by Cullen, of Typhus Mitior and Typhus Gravior.

* That some estimate of the comparative frequency of the several local lesions which arise in the progress of fever may be formed, the result of 521 cases selected from the journals of the London Fever Hospital is annexed.

Cases in which the fever was not apparently complicated with local inflammation in any organ	163
Cases complicated with cerebral affection	114
thoracic affection	103
abdominal affection	71
cerebral and thoracic affection	26
cerebral and abdominal affection	30
cerebral, thoracic, and abdominal affection	14

In typhus mitior the febrile symptoms are mild, though it is evident from the intellectual disorder and prostration, that the nervous system is much affected. It is probable that in these cases, especially at the commencement, there is no inflammatory action in the brain,—the whole phenomena, viz. great languor, feeling of debility, muscular prostration, soft feeble pulse, giddiness, intellectual dulness, and transient delirium, being the result of the peculiar operation of the febrile causes on the nervous system.

Subacute inflammation of the brain often supervenes on this condition of the nervous system; and when this takes place, the more prominent symptoms of cerebral inflammation are recognized; and to the difference in the intensity of the cerebral affection may be traced the infinite variety of nervous symptoms which individual cases present.

Of the lesions in other organs which arise in the more severe cases of typhous fever (*typhus gravior*), congestion or inflammation of the mucous membranes, bronchial and intestinal, and inflammation of the parenchyma of organs, are the most important. The congested state of the capillaries of the mucous membranes, the blood being at the same time in a state which favours its transudation, occasionally gives rise to hemorrhage from different parts, more frequently, however, from the bowels than from either the nose, lungs, or any other cavity; and when the hemorrhage is excessive, the already exhausted powers of the patient are often irrecoverably sunk. A similar hemorrhagic action is not unfrequently manifested in the skin, in the form of small red spots (*petechiæ*). These vary in colour and size; they are sometimes of a bright red, in other cases of a darker red or even purple hue, and generally distinct; in some instances the spots cohere, and form an ecchymosis of greater or less extent. These patches are termed *vibices*.

In cases of still greater malignity, carbuncles and gangrenous inflammation of the skin, more particularly on those parts which are subjected to pressure, often arise: and the lymphatics, more particularly the submaxillary, cervical, and inguinal, and in some cases the parotid glands, become inflamed, the cellular substance in which they are imbedded not unfrequently suppurating, and thus forming what some writers have considered a critical abscess. At particular seasons also, erysipelas is very apt to supervene, but more particularly in hospitals,—erysipelatous inflammation rarely supervening on fever among the better classes.

From the peculiar changes which take place in the blood in typhous fever, and to which many pathologists of the present day ascribe all the phenomena, the secretions are more vitiated than in the other forms. This is exemplified in the remarkable fetor of the breath and perspiration, which is so peculiar as to be readily recognized, and in the evacuations from the bowels, which are always exceedingly offensive.

After these general observations, we are prepared to enter on the particular symptoms.

Symptoms of typhous fever.—It has been already stated that a distinction of typhous fever has been made, founded on the difference of intensity of the symptoms. The invasion of the milder form (*typhus mitior*) corresponds very much with that of common fever. The patient complains of giddiness, listlessness, and indisposition to exertion, alternate chills, and hot flushes, with uneasiness or pain at the pit of the stomach. These precursory symptoms are succeeded by pain in the back and loins, burning heat of the skin, flushing of the face, sense of weight in the head or giddiness, noise in the ears, and disposition to quietude. The expression of the countenance indicates intellectual dulness. The pulse is frequent and soft; the digestive organs are deranged; food is disliked; cold acid drinks are relished; the tongue is coated with thin white fur, which becomes gradually thicker and of a brown colour, sometimes it is clean but morbidly red; the mouth is clammy from superabundant secretion of mucus in the throat and mouth; sometimes there is pain in the epigastrium, nausea, and vomiting. Towards the third or fourth day, the symptoms in the brain become aggravated, the head feels more heavy, the mind is more confused; the patient, restless and watchful through the day, becomes delirious at night, while, according to some writers, an eruption of miliary or larger vesicles, with intervening redness of the skin, appears on different parts of the body.

The disturbance in the intellectual powers gradually increasing, the delirium, which was only perceptible at night, is observed to recur at intervals during the day; the hearing becomes dull; the patient more torpid; the answers given to questions evincing hesitation and marked indifference to surrounding objects. About this period epistaxis occasionally takes place; *petechiæ* appear in different parts of the skin, more especially on the chest, abdomen, arms, back, and thighs. This petechial eruption is not constantly observed in typhous fever, but seems to form an occasional characteristic of some epidemics; and from this circumstance the disease has been termed *petechial fever*. Dr. Stoker states that, of five hundred and forty patients received into the Cork-street Hospital, three hundred and eighty-six had *petechiæ*. In the London Fever Hospital, the cases now (June 1832) under treatment have almost invariably the petechial eruption.

These spots or exudations of blood are not confined to the skin, but spread over the serous and mucous membranes; hence, in fatal cases of petechial fevers, the surface of the viscera have been found studded with small bloody effusions.

The condition of the alimentary canal in typhous fever is various, not only in different individuals, but in different seasons and epidemics. Sometimes the bowels are torpid throughout the whole period of the dis-

case; in other cases there is diarrhoea from the beginning, which only disappears with the cessation of the fever. The urine is always scanty and high-coloured, and towards the decline usually deposits a sediment.

This is the usual progress of typhous fever for the first nine or ten days, about which period another train of symptoms appear—those denoting collapse or failure of the powers. This stage is announced by the decline of the previous more acute symptoms—by the pulse becoming more rapid and soft—the tongue dry and brown, often tremulous and protruded with difficulty—by the incrustation of the teeth with sordes—by the increasing intellectual disorder, indicated by the more constant low muttering delirium, and the greater insensibility and deafness—and by the condition of the muscular system, evinced by muscular tremor and subsultus tendinum, and in some cases irregularity or intermission of the pulse, by the patient lying sunk on his back, or sliding to the foot of the bed, the muscles being unable to support the body even in the horizontal posture.

From the stage of collapse the patient not unfrequently recovers, the period at which this favourable change takes place being very uncertain; it occurs in some instances about the fourteenth or fifteenth day, but often not till a much later period, depending on the more or less tedious character of the epidemic, and the complications which may have arisen. It is announced by progressive amendment in the symptoms, by the delirium and other symptoms of sensorial disturbance disappearing, the patient enjoying intervals of refreshing sleep; by the countenance improving, and the evacuations being passed consciously, the pulse becoming more slow, the skin cool and soft, and the tongue more clean at the edges and moist over the body. When these favourable appearances are observed, the convalescence, though slow, is gradually established, the individual, however, remaining in a very weak state for a long time.

The progress of the disease to a fatal termination is indicated by coma, more or less profound, hiccup, retention of urine, or involuntary evacuation of the urine and stools, and tympanitic distension of the abdomen.

A modification of typhous fever has been described by Dr. Armstrong under the name of *congestive typhus*, which, in the opinion of this writer, differs from the more common forms of the disease. This theory presumes that the functions or structure of some important organ are deranged by an almost stagnant accumulation of blood in some part of the venous system. There is no re-action; the system does not recover, or only imperfectly, from the first shock or stage of oppression, the energies of the system being either nearly extinguished by the venous congestions, or so much oppressed as to be unable to create excitement. The local accumulations of blood in the veins are supposed to obstruct from the beginning the common series of febrile phe-

nomena; and there is, in consequence, either no morbid heat of skin, or the heat becomes concentrated in some particular parts of the body, while on others it is below the natural temperature. This form, according to this author, is characterized by the sudden invasion, by the overpowering lassitude, muscular feebleness, deep pain, giddiness, or sense of weight in the encephalon; pallor of the countenance; anxious breathing; cool skin; low, struggling, and variable pulse; irritable state of the stomach; mental dulness, apprehension, and confusion, rather than delirium; heavy suffused eye, as if from intoxication or want of sleep; rough, foul, and dry brown tongue; the bowels, torpid in the beginning, becoming in the advanced stage generally loose; the stools copious and involuntary, and accompanied with inflation of the abdomen. The general torpor causes diminution or suspension of the secretions, and such deficiency of cutaneous excitement, that if blisters be applied, they either do not act at all, or so defectively, as to leave an appearance as if the part had been slightly seared by a heated iron. Petechiæ generally appear earlier in this than in any other varieties of typhus, and in the last stage there are sometimes gangrenous spots on the extremities, oozing of blood from the mouth and nostrils, and hemorrhage from the bowels.

Dr. Armstrong has described several modifications of congestive typhus, all of them recognized by the depressed state of the heart and circulation—the uneasiness in the head—the præcordial anxiety—the peculiar condition of the temperature and skin—the total want of excitement, or its partial and unequal development—the suspended or vitiated secretions—and the local load and general oppression.*

When typhus fever becomes complicated with local inflammation, constituting the *typhus gravior* of Cullen and others, the symptoms from the commencement are more severe, and when the cause of this severity is investigated, it will be found to depend on the inflammation which has arisen either in the brain, in the lungs, or intestines.

1. The cerebral complication is known by the more marked and early affection of the brain—the more deep or severe pain, or sense of weight in the head, giddiness, or oppression—suffusion of the eyes—more constant delirium, and disposition to coma—muscular tremor and subsultus tendinum—soft, rapid, and occasionally intermitting pulse—and involuntary evacuations.

2. There is invariably bronchitis in the more severe cases of typhus. It is generally very obscure from the absence of the more prominent symptoms, so that if it be not indicated by cough and accelerated breathing, there is nothing to lead to the suspicion of pulmonary disease. The application of the stethoscope, however, will enable the practitioner

* Practical Illustrations of Typhous Fever, by John Armstrong, M.D.

to discover the bronchitis, sometimes confined to an entire lobe, or in more severe cases extending over both lungs. Not unfrequently, but especially in the winter, and during some epidemics, pneumonia supervenes, and rapidly destroys life.

3. The state of the intestinal canal forms another important feature in the class of fevers under consideration. The symptoms by which the intestinal affection in fever is attended, we have seen to be very obscure; but its existence may be inferred, when the tongue is morbidly red at the point and margins, while the body is dry, fissured, and covered with dry, brown, or black incrustation; when the belly is tympanitic, and there is hemorrhage from the bowels. There may or may not be abdominal tenderness on pressure; more commonly, and particularly when there is much sensorial disturbance, the sensibility is so blunted that the patient does not feel inconvenience even from firm pressure.

Morbid anatomy of Continued Fever.—Though morbid anatomy has not yet unfolded the true nature of fever, more sound views of its pathology and treatment have been obtained, by comparing the symptoms during life with the morbid appearances found on dissection. Before examining the morbid appearances in each organ, it is necessary to premise, that in some instances of sudden and early death from fever, no changes of structure sufficient to account for the fatal issue have been discovered. We are to conclude, therefore, that in these cases the duration of the febrile excitement had been too short to produce any appreciable alteration of structure in any organ.

1. *Morbid appearances in the brain.*—The *dura mater* is scarcely ever altered in appearance, though in some cases a small quantity of serous fluid has been found between this membrane and the arachnoid. Louis observed in one case the inside of the *dura mater* lined with a thin pseudo-membrane.

In the majority of cases, the *arachnoid membrane* exhibits traces of previous inflammatory action; it is sometimes simply vascular, in other cases thickened and opaque, with more or less effusion between it and the *pia mater*. The fluid varies in colour and consistence. It is generally transparent and colourless; but in instances in which the previous inflammatory action has been more intense, it is opaque, of a light straw colour, and of greater consistence, approaching to the nature of coagulable lymph.

In the ventricles there is generally a small quantity of serous fluid, varying from one or two drams to half an ounce; it rarely amounts to an ounce.

The vessels of the *pia mater*, which often adheres in points to the arachnoid membrane, are generally more numerous, distended, and tortuous than in the natural state of this membrane, especially in those cases in which the other parts of the brain exhibit traces of vascular turgescence. According to Louis, the injection of the *pia mater* is greatest

in the rapidly fatal cases, and serous effusion in those of which the progress has been more slow.

The consistence of the *substance of the brain* in fever is variable; sometimes it is extremely soft, so that it lacerates easily; in other cases it is unusually firm. It is difficult to determine how far these opposite states indicate of themselves the previous existence of inflammation. Louis does not seem inclined to believe that either condition is to be considered as the result of inflammation, as the change is uniform throughout the whole brain, and the symptoms during life do not bear an invariable relation to the appearances in the brain after death.

Injection of the substance of the brain is not unusual, the vascular turgescence being observed in a larger proportion of cases in the medullary than in the cortical portion. The blood-vessels are not only more distended, but more numerous, as may be observed on making a section of the brain so as to expose the centrum ovale, when numerous bloody points, the orifices of divided arteries, are interspersed, giving the section a dotted appearance.

The *cerebellum* seldom exhibits any alteration, if we except that of the membranes at the base of the brain, and the effusion with which it is frequently associated. A slight degree of softness of its substance has in some cases been observed.

The *spinal cord* has not undergone that minute investigation which would enable us to speak with certainty as to its general state in fever. When the medulla oblongata is divided, so as to allow the removal of the brain, a quantity of serous fluid escapes from the vertebral canal in those cases in which there has been considerable effusion in the ventricles. The membranes which envelope the spinal cord have been occasionally found vascular, the substance of the medulla spinalis being at the same time injected and softened.

With regard to the proportion of cases of fever in which lesions of the brain have been discovered after death, Louis, in his recent work, states that besides the case in which the inside of the *dura mater* presented a thin pseudo-membrane, in *four* there was a little fluid between the *dura mater* and arachnoid; in *more than half*, the sub-arachnoid cellular tissue was infiltrated with serosity, and in *one half* the *pia mater* was injected with blood. In *three-sevenths*, the cortical substance was redder than natural; in *six-sevenths*, the medullary matter was injected,—these latter appearances being most striking when death took place at an early stage; in *six* cases, the density of the brain was slightly increased; in *five*, it was diminished. Of fifty-four cases examined at the London Fever Hospital, thirty-seven exhibited evident traces of previous inflammation of the brain.

2. *Morbid appearances in the chest.*—The structure of the *larynx* in fever is generally healthy, unless, as occasionally happens during the period of convalescence, laryngitis or tra-

cheitis supervenes. In the former case, the glottis is found contracted in consequence of œdematous swelling or serous infiltration of the submucous cellular tissue of the epiglottis, or rima glottidis: sometimes the larynx is lined with a thin layer of recent lymph, extending into the trachea. In the latter, the peculiar membrane of croup is observed.

Inflammation of the *pharynx*, followed by abscess, occasionally takes place, and when the purulent collection occurs in the vicinity of the glottis, the pressure gives rise to the ordinary symptoms of laryngitis. We have known these cases terminate fatally.

In examining the state of the *lungs*, it is necessary to guard against a source of fallacy. The blood appears chiefly in the posterior portion of the lungs; this circumstance has given rise to the idea that the patient had pulmonary engorgement during life. This pseudo-morbid appearance is readily produced by the gravitation of the blood after death, favoured by the position of the body; indeed, were the body placed immediately after death in any other, we should find a similar congestion in the portion of lung which is most dependent.

When bronchitis has existed during fever, the *mucous membrane* exhibits more or less vascularity; this is most perceptible in the trachea and larger bronchial tubes, though, perhaps, throughout the whole extent of one lobe, the bronchial membrane has a more or less dark red swollen appearance, very different from the pale pink colour observed in its healthy state. When the symptomatic bronchitis has been severe, the bronchial membrane of both lobes appears red, and often considerably swollen and thickened, while the smaller tubes are filled with mucus or muco-purulent fluid.

In fatal cases of fever complicated with pleuritis, adhesions between the *pleura pulmonalis* and *costalis*, with or without effusion of coagulable lymph on the inflamed surfaces, are the usual morbid appearances. Sometimes there is effusion of serous fluid into the pleural cavity, the fluid being frequently mixed with portions of coagulable lymph, which render it more or less turbid.

When the *substance of the lung* has been inflamed, the appearances vary according to the intensity of the pneumonia. When the fever proves fatal in the first stage, the lung is increased in density, and infiltrated with serous or bloody fluid. When it has proceeded to the second stage, it is solid and dense, and no longer crepitates. In a still more advanced stage, the pulmonary structure assumes a granular appearance, and pale yellow colour, from purulent infiltration. In some instances that peculiar lesion known by the term *pulmonary apoplexy* has been observed.

Lesions of the *heart* are very rarely observed in fatal cases of fever. In some instances, but more especially in the fevers of hot climates, which run on to a fatal termination with great rapidity, the muscular structure has been found

softened and attenuated so as to be easily lacerated. Louis states that this affection was uniformly greatest in the instances of rapid death, and was invariably conjoined with a hurried, fluttering, irregular, and feeble pulse. This softening is generally confined to the left side of the heart, though sometimes both sides have been found affected. Other morbid changes have also been observed, but in those instances the organic disease has always been of long standing, the fever having supervened in the progress of the cardiac affection.

The internal membrane of the *aorta* and some of the *larger arteries* occasionally exhibits a bright red colour. This redness, which occurs in patches of various sizes, is not the product of inflammation, but only the effect of *staining*. This has been proved by the fact, that this appearance may be easily produced by filling a portion of a large artery with blood, and confining it by means of ligatures. Some pathologists have mistaken this staining for arteritis.

3. *Morbid appearances in the abdomen.*—The occasional occurrence of abscess in the submucous cellular tissue of the *pharynx* in fever has been already mentioned. The *œsophagus* is generally unaffected. Some writers have alluded to superficial ulcerations in both the *pharynx* and *œsophagus*. Such morbid appearances however are to be regarded only as occasional secondary affections.

The alterations which take place in the *alimentary canal* are chiefly in the mucous membrane, and follicles of the small intestines.

When the cavity of the abdomen is laid open, the stomach and colon are in the majority of instances considerably distended with flatus—the diameter of the small intestines, particularly in those portions where there are lesions, being contracted, and of a dark colour.

On examining the internal mucous coat of the *stomach*, it occasionally exhibits some deviation from the healthy state. Louis affirms that in thirteen of forty-six cases examined, the stomach was quite healthy in colour and consistence. In some instances it is injected in patches of various extent; in others, it is partially and sometimes generally softened and attenuated, so that the mucous membrane is easily detached from the subjacent cellular tissue.

In a few instances, ulceration of the stomach has been found. This occurs in a larger proportion of cases in the fevers of France than in those of Great Britain. Andral states that ulceration of the stomach occurred in one-tenth of the cases examined by him at the Hôpital de La Charité; Louis found this lesion in one-twelfth of those he inspected at the same establishment. In the Fever Hospitals of Britain, this lesion is scarcely ever observed, though we find in many cases appearances indicative of previous inflammatory action in the mucous membrane, viz. redness and softening,

It is seldom that the mucous membrane of the small intestines is sound through its whole extent. The *duodenum* rarely exhibits any trace of disease, and may, therefore, be considered less frequently affected in fever than any portion of the alimentary canal. In the remaining portion of the small intestines (*jejunum* and *ileum*) we find more uniform lesions; in the more rapidly fatal cases, or when the whole force of the disease has centred in another organ, the mucous membrane retains the natural pale pink colour. In general, however, we observe portions of a greater or less extent, uniformly reddened, the tinge differing from a light red vermilion to a deep brown. The redness is usually deeper in the valves than in the intervening spaces, so that if these valves be drawn out, the intensity of the colour very much diminishes or altogether disappears. This red injected appearance of the villous surface of the intestines is generally followed by intestinal hemorrhage. Sometimes, instead of this uniform redness, the membrane is studded with clusters of small red points or dots, which apparently arise from injection of the capillaries, or in some instances from effusion of blood beneath the mucous membrane. The red colour of the membrane, however, is by far the more common appearance, and is more uniform and extensive in the portion of the ileum adjoining the cæcum: it varies in extent in different subjects, often extending for several feet, occasionally over one-half, or even the whole of the small intestines. In the more advanced stage of inflammation of the mucous membrane, the colour assumes a grey tinge, and when this is observed, it always indicates protracted fever. Louis states that he scarcely ever saw the grey colour of the mucous membrane in persons who died before the twentieth day of fever, more generally in those who died from the twentieth to the thirtieth day, or even at a still more advanced period of the disease; hence it has been supposed that the grey colour occurs when the redness of inflammation is passing off, and the mucous membrane is about to resume its healthy colour.

The consistence of the mucous membrane of the intestines is not always uniform. In the majority of instances it retains its natural consistence; in other cases the inflammation produces thickening and pulpiness of the mucous coat. Though softening has been observed in a small proportion of cases only, it is more frequently met with than thickening, and has been more particularly remarked when the fever had been long protracted. It does not, however, appear to be the necessary consequence of inflammation, as it occurs in some cases without redness; that it occurs with both redness and thickening of the membrane, cannot be denied; but, as it is more frequently noticed without either of these conditions, we must conclude that, although we are unable to explain the precise circumstances under which softening of the mucous membrane of the bowels arises in fever, it is not the product of inflammation. We know

that it may be produced very soon by corrosive poisons. Mr. Brodie found the stomach of a dog, to which two grains of the oxy muriate of mercury had been given, remarkably softened half an hour after the poison had reached the stomach.

Besides these morbid states of the mucous membrane, vegetations of a red or brown colour, and of extremely soft consistence, are occasionally met with. They lie one above the other, projecting perhaps three or four lines above the surrounding membrane: they are not very common. We have seen only one case at the London Fever Hospital, and in this subject the vegetations occurred in the lower portion of the ileum. Andral states that he met with them only in the large intestines. Orfila met with a considerable number in the stomach of a person who had taken cantharides.

The tendency of inflammation of the mucous membrane of the intestines to pass into ulceration has been observed by every modern pathologist who has examined the various lesions which arise in the progress of fever.

These ulcerations in some cases succeed to simple inflammation of the villous coat, in which case the ulceration takes place in one or two points, generally in the centre of the inflamed patches; these points become by degrees more numerous and extensive, and at length coalesce so as to form a patch of greater or less extent. The same process may be going on in different portions of the membrane at the same time; and if it happen that the ulceration commences in contiguous portions of the bowel, one or more patches often cohere, and thus form an ulcer of considerable size.

The most common form of intestinal ulceration, however, is that which succeeds to inflammation of the mucous follicles of Peyer and Brunner. These follicles or glands, which in their natural state are very minute, vary in number and size in different situations. At the pyloric extremity of the stomach they are numerous, but distinct or isolated; hence called *glandulæ solitariae*, or after the anatomist who first particularly described them, *glandulæ Brunneri*. They gradually diminish in number towards the extremity of the duodenum, in which situation they are larger and more apparent than in any other portion of the bowels. In the jejunum and ileum they become more numerous and form into groups; hence they are called *glandulæ agminatæ*, or *Peyeri*, (Peyer being the anatomist by whom they were first observed.) They become exceedingly numerous towards the lower third portion of the ileum.

The greater vitality of these follicles, compared with other parts of the mucous membrane, renders them peculiarly liable to inflammation and disorganization; hence we find that, according to the stage of fever, hypertrophy, redness, and ulcerations of these follicles are the only morbid appearances. M. Bretonneau has distinguished this form of intestinal inflamma-

tion by the term *dothineria*, (from *δοθινά*, *pustula*, and *ἰντερον*, *intestinum*.) The glands of Brunner are less frequently diseased than those of Peyer, and if the statement of Louis be correct, viz. that, in other acute diseases, inflammation of the villous coat, as well as enlargement of the mucous crypts or glands of Brunner, are not unfrequently observed, though not so commonly as in fever, but that disorganization of Peyer's glands are never met with, except in some forms of fever, the changes which take place in these follicles (*glandulæ agminatæ*) may be admitted to be peculiar to certain types of fever, and to constitute their true pathology.

With regard to the situation of these ulcerations, it may be stated that they occur in every part of the intestinal canal, from the cardiac extremity of the stomach to the rectum. They occur, however, more frequently in some portions of the bowels than in others. For instance, they are comparatively infrequent in the stomach, still more rare in the duodenum and jejunum: the most common situation is in the lower third portion of the ileum. In the colon they are occasionally found, though less frequently than in the small intestines.

From the following table drawn up by Andral, an idea may be formed of the relative frequency of intestinal ulceration in different parts of the canal.

Seat of Ulceration.	Number of Cases.
Stomach	10
Duodenum ..	1
Jejunum	9
Ileum (lower portion of).....	38
Cæcum	15
Colon { Ascending	4
Transverse	11
Descending ..	3
Rectum	1
Total	92

The ulcerations also vary in several particulars, especially as to number, aggregation, size, and shape. In the stomach there is in general only one solitary ulcer, seldom more than two. In the lower portion of the small intestines they are more numerous, and situated nearer each other than in the upper, in which situation there is often a considerable distance between them: in the ileo-cæcal valve they are generally so closely situated as to form a large patch of ulceration: they are less confluent in the cæcum. As to size, some are not larger than an ordinary pin-head; the more general size is from a split garden-pea to half a crown; but between these sizes there is every intermediate gradation, the structure of the intestine being sometimes completely destroyed for several fingers' breadth above the cæcum, where the largest ulcerations generally occur.

The form or shape of these ulcerations is also various; some are oblong, having their greatest diameter according to the length or breadth of the intestine; sometimes they are circular, occasionally linear. Their number,

size, and depth depend on the duration of the fever. In general, when patients die within the first fourteen days, the disease in the mucous membrane, or in the follicles, has not advanced to the stage of ulceration, though from every appearance this subsequent stage would soon have taken place.

When the ulcerations are numerous, large, and deep, we may presume that the fever is of considerable duration,—that it has advanced beyond the third week. In the same portion of intestine, too, every successive change may often be observed: thus we find in one part the mucous membrane red and swollen; in another, the mucous follicles enlarged; in a third, abrasion of the membrane or follicular ulceration.

Sometimes these ulcers extend chiefly in breadth, but more frequently in depth, destroying in succession the coats of the bowel. When the diseased process has commenced in the follicles, a small spot of ulceration is observed on their summit; the ulcers then gradually extend both in breadth and depth, so as to expose the muscular coat, which then becomes the floor of the ulcer: in process of time the muscular coat is destroyed, the peritoneal covering alone remaining; and should the patient survive, this becomes gradually thinner by ulcerative absorption, and at length gives way, constituting *intestinal perforation*: the escape of the contents of the bowels through the aperture being followed by rapid peritonitis and death.

The symptoms which indicate intestinal perforation are sudden excruciating pain and increased distention of the belly; sometimes vomiting; small, rapid, feeble pulse; shrinking of the features; cold sweats; and death follows generally within thirty-six hours, though some individuals have existed for a longer period.

When the brain has been much affected, the patient is so insensible as not to feel pain in the abdomen, even when the perforation takes place: in such instances it may be suspected from sudden alteration in the features, rapid distention of the abdomen, and small contracted quick pulse. In some instances, the adhesion of the portion of the intestine, at the point where the ulcerative process is going on, to some adjoining viscus, has prevented the peritoneum giving way, and the consequent effusion of the intestinal contents into the abdominal cavity.

It appears, as we have already observed, that intestinal ulceration is more common in the fevers of France than in those of Britain, and that they occur more frequently at some seasons than at others. It is probable, too, that they are found in a larger proportion in populous places, as in the large towns, than in villages or the open country. Of fifty-four cases examined at the London Fever Hospital, (1828-1829,) intestinal ulcerations were discovered in sixteen; and in ninety-two cases of two hundred and twenty-nine treated at La Charité by Lerminier. On what this difference depends, it is not easy to determine.

With regard to the cicatrization of intestinal ulcers, there is now no longer any doubt that this reparative process does take place. Besides the well authenticated example in the case of the late celebrated Beclard, in whose stomach a cicatrized ulcer was discovered at the small curvature, we have the testimony of Troillet, Louis, and other pathologists, on this point; and though we ourselves have never witnessed an unequivocal instance of genuine cicatrix, the minute detail, by those writers, of the various stages observed during this process, and their accurate description of the appearance of intestinal cicatrix, leave no longer any doubt on this subject; but from the want of diagnostic symptoms to indicate the existence of intestinal ulceration, it cannot be determined in what proportion of cases this reparative process takes place. It is probable, however, that it is a rare termination of such lesions.

The *colon*, in fatal cases of fever, is considerably distended with flatus; it appears to be the portion of intestine in which tympanitic distension usually occurs.

The internal or mucous surface sometimes exhibits evidence of previous inflammation in the red, softened, or thickened state of this membrane. The mucous follicles are occasionally enlarged; and ulcerations, chiefly in the *cæcum*, are now and then observed.

The *mesenteric glands* are almost invariably diseased: when there is no intestinal ulceration, they are simply enlarged and indurated; when ulceration of the bowels has taken place, these glands, besides being enlarged, generally contain pus.

The *external absorbents*, especially those situated in the neck, axilla, and groin, are occasionally enlarged and indurated. In some epidemics parotid buboes are not uncommon, indicating a malignant form of fever.

The only alteration in the *liver*, which may, perhaps, be deemed peculiar to fever, is softening; and this is only occasionally observed. In those instances, it is of a pale colour, and so soft as to be very easily lacerated.

The *spleen* is very generally altered in structure in fever. This alteration consists in unusual softness, in some instances to such a degree that the organ is reduced almost to a pulp, and breaks down on the slightest pressure: it is generally accompanied with enlargement, though seldom to any considerable extent, while its colour is changed to a very dark purple or a reddish black.

This softened state of the spleen has been observed in every stage of fatal cases of fever; in those who perish early, as well as in those in whom the disease is more protracted; it does not appear to have an inflammatory origin, since its capsule is generally sound. From this extreme softness in some forms of fever, more especially typhoid fever, and in diseases of putrescency, such as scurvy, it is probable that a morbid condition of the fluids has a peculiar effect on the structure of

this organ, though we know of no symptoms which indicate this particular lesion.

In one case which came under the care of the writer of this article, at the London Fever Hospital, a small circumscribed abscess was found in that portion of the spleen which is connected with the diaphragm. In this instance symptoms of pleurisy of the left side arose in the progress of fever, which did not yield to the ordinary treatment. The patient eventually died; and on dissection, a small tumour of the size of an egg was observed in the centre of the diaphragm, which gave at first the idea of diaphragmatic hernia. On more close inspection it was discovered to be an abscess in the spleen, which had formed an attachment to the diaphragm, through which it had so far penetrated as to be covered only by the thin transparent pleura. It appeared just about to burst into the left side of the chest. The general structure and size of the organ were otherwise healthy.

Pathology of the fluids in fever.—That the fluids are changed in fever is evident from the altered state of the various secretions, as well as from certain appearances which have been observed in the blood itself. This subject, though of the utmost importance, has been hitherto almost entirely neglected, probably in consequence of the pathologists of the present day being more disposed to investigate the morbid changes which take place in the solids, and consequently to trace the causes of the phenomena of fever to disease in them, rather than to any alteration in the blood itself.

The doctrines of humoral pathology which prevailed for many centuries were not founded on direct experiments, but on vague conjecture, from observation of the constant and uniform vitiation in the fluids. Chemical analysis in those days had not attained the perfection necessary to detect the various changes which the blood and fluids were supposed to undergo; and, in later times, the acknowledged difficulty of such experimental inquiries, with the zeal with which morbid anatomy is cultivated, will account for the slow progress of this department of pathology.

That the blood does undergo changes in fever was always conjectured: that certain changes precede its development, and that certain alterations in its component principles do arise in its progress, is not only highly probable, but, as has been already stated, some modern pathologists do not hesitate to affirm that a vitiated state of the blood is the origin, source, or proximate cause of the disease.

It has been often observed by practical physicians, that the blood drawn from persons labouring under fever differs according to the type and the duration of the disease. In cases which bear the inflammatory character, the coagulum is firm, the fibrine abundant, or in greater relative proportion to the water and albumen: in some instances the coagulum is so dense that little or no serum is separated.

This condition of the blood may or may not be accompanied with the buffy coat.

There appears, however, in the progress of fever, to be a gradual diminution of the fibrinous principle; the coagulum being not only small in proportion to the serum, but of a loose soft texture. Upon what this diminution of the fibrine, and of the force of aggregation by which its particles are kept together, depends, neither physiology nor chemistry has yet discovered; all that in the present state of medical science we do know on this point, are the facts stated. Dr. Clanny has endeavoured by well-contrived experiments to determine with accuracy the relative loss or diminution of fibrine at the various periods of fever, and certainly his investigations on this curious subject deserve attention.*

The changes which take place in the secretions in the progress of fever, and which are so evident to the senses, depend in some measure on the general disturbance which takes place in every organ of the body, as well as on the condition of the blood. It is evident that if this fluid, from which all the secretions originate, be in a morbid state, the fluids which are eliminated from the parent source, must likewise be in an unhealthy state. The changes which the individual secretions undergo in fever have not been ascertained by chemical experiment, the knowledge we have of their vitiation being derived exclusively from observation.

Crisis of Fever.—From the earliest periods of medicine, the termination of acute diseases, more especially fevers, was observed to be preceded or accompanied by certain appearances or symptoms which indicated a favorable or unfavorable termination of the malady. Hence the origin of the term *crisis* (from *κρίσις*, judgment), and the days on which these changes occurred were called *critical days*.

The crisis was regarded as salutary when an evident amendment or complete cure accompanied or followed the change; *perfect* when there was an entire cure of the disease; *imperfect* in the case of simple amelioration; and false when certain appearances, such as hemorrhage, petechiæ, colliquative sweats, inflammation of the parotids, and carbuncles appeared, as these only portended a more dangerous and probably fatal form of fever.

Those who embrace the humoral pathology of fever imagine that the termination of the symptoms is produced by some great effort of the system to relieve itself, following the Hippocratic doctrine, that there being always a morbid matter to be expelled, nature was ever endeavouring either to attenuate this supposed morbid material, or to discharge it from the system. The solidists on the other hand contend that the solution of fever is effected by the treatment applied to the local affection, of which the fever is supposed to be symptomatic. Without entering into this discussion, we may observe that the crisis of

fever often takes place without sensible evacuation: in a large proportion of cases, however, it is preceded or accompanied by some change in the secretions, or by diarrhœa or hemorrhage.

The urine is well known to exhibit certain alterations in the progress of fever. In the early stages it is diminished in quantity, but without any change in its colour or chemical properties. As the symptoms advance, the urine becomes darker in colour, but does not deposit a sediment till the fever begins to decline, when it is increased in quantity, and deposits a cloud or sediment on cooling. This urinary deposit, which is sometimes copious, appears in the bottom of the vessel some hours after the urine has been voided: from its resemblance to brickdust it has been called *lateritious*, and by evaporation may be collected in minute crystals of lithate of ammonia. This sediment is by no means peculiar to patients labouring under fever, but is often observed in the urine of healthy persons, or in those whose function of digestion is impaired. In other instances the sediment is of a pinkish white colour, and to this deposit, which according to Dr. Wilson Philip consists of the phosphates of the urine, the term *furfuraceous*, or *branny*, has been given. He regards both these urinary deposits as indications of returning health, and particularly of the renewal of a free secretion by the skin, which in fevers is generally a favourable symptom. In some fevers terminating favourably, there is an unusual tendency to sweat which only exhausts the strength. In these the furfuraceous sediment is observed, but without removing the fever. This is the case in hectic fever.*

The connexion of the favourable termination of fever, more especially intermittents, with free perspiration, was so often remarked by the ancients, that it gave rise to the practice of treating the disease by means calculated to induce diaphoresis, a practice which was followed by the most injurious consequences. They believed the abatement of the symptoms to be entirely owing to the free action of the vessels of the skin; and that consequently, if

* Dr. Wilson Philip states that the following are the only appearances of the urine, if we except those it assumes in consequence of morbid affections of the urinary organs, which can be distinctly marked:—the pale urine without cloud or sediment—the pale urine with a slight cloud appearing a few hours after it has been passed—the high-coloured urine remaining clear, or having a light cloud formed in it, and depositing usually, a considerable time (from four to twelve hours) after it has been passed, a red crystallized sediment—the high-coloured urine becoming turbid after it has been passed for a short time (from half an hour to two hours), and depositing a light-coloured, sometimes pinky sediment, now and then (after the urine has stood for a longer time) mixed with more or less, if the light-coloured sediment is copious, never with much, of the red crystallized sediment. In almost every disease, as well as in health, the urine occasionally assumes all these appearances.

* Lecture on Typhus Fever.

sweating could be induced, it would have a salutary tendency. On this point it is only necessary to observe, that however beneficial moderate spontaneous perspiration undoubtedly is, permanent abatement of the febrile symptoms seldom follows diaphoresis when artificially induced. When the sweating is so profuse as to induce exhaustion, or when it is partial or clammy, it is unfavourable; and though as a general rule, when critical sweats appear, little should be done, if the strength be evidently lowered, or if there be not corresponding amendment in the general symptoms, they should if possible be checked.

It is remarkable, however, that in those kinds of fever in which there is great weakness, profuse long-continued sweating has been often observed to be most salutary. We are informed by Dr. Donald Monro, that in the petechial fever sweating often continued with the best effects for three or four days. Hoffmann also observed, as a peculiarity of this fever, profuse cold sweats of an acid smell, continuing for days and nights, and proving (apparently) a salutary crisis.

When moderate diarrhœa comes on towards the termination of fever, it is generally a favourable circumstance, and ought not to be interfered with. When there has been a disposition to relaxation of the bowels throughout the disease, which is not uncommon in some epidemics in which gastric symptoms predominate, or at particular seasons, the irritation commonly subsides spontaneously; should it even continue through the period of convalescence, provided it do not interfere with the recovery of the patient, it is only necessary that the diet and general management be duly regulated. When the diarrhœa appears to retard recovery, and produce gradual emaciation, the practitioner should never lose sight of the possibility of the affection being the result of inflammation of the mucous membrane of the bowels, or of other intestinal lesions, and therefore requiring the most vigilant care. From these observations it appears, that although diarrhœa does occasionally come on towards the close of fever, and in such instances may be said to be critical, yet no positive conclusions can be drawn from this symptom—that when moderate it may be salutary, when excessive it retards recovery, and in many cases appears to indicate some of those intestinal lesions which generally prove fatal.

Though critical hemorrhagies are mentioned by many of the older authors as occasional occurrences in fever, we confess that in our individual experience we have never witnessed such a crisis of fever. The inference is, that the occasional hemorrhagic action (more common in the fevers of hot countries) which has been observed in some cases to take place spontaneously, and to be followed by a salutary effect, has been improperly termed *critical*. We have repeatedly observed such spontaneous hemorrhage from the nose when there was considerable cerebral affection, and always re-

marked the great relief which followed this salutary evacuation; but we have never met with an instance in which the fever disappeared with the epistaxis. In typhous fever, hemorrhage from mucous surfaces and from the skin (petechiæ) at any period of the disease, but more particularly in the advanced stages, is not unusual. These hemorrhages are never critical; they tend to lower the already exhausted powers of the patient, and always indicate an unusually severe, if not a fatal form of fever.

Enlargement of the absorbents (more especially of the cervical and parotid glands) occasionally takes place towards the termination of fever. This is more common in some epidemics than at other times, and though resolution generally takes place when the inflammation extends to the cellular tissue surrounding the gland, it terminates in suppuration. Abscesses occasionally form in different parts of the body towards the decline of fever, and have therefore been regarded as critical.

Eruptions of the skin have also been observed towards the decline of fever. The appearance of aphthæ on the tongue, lips, and inside of the mouth, has been thought an unfavourable circumstance in fever, as indicating debility. Though we do not think the supervention of any eruption a desirable event, we have never observed an unfavourable result in such cases as have been accompanied with aphthæ.

Herpes about the mouth and ears towards the termination of fevers is to be regarded as a salutary crisis.

The ancients also believed that fevers had a fixed or determinate duration, and that these terminations happened on certain days in preference to others. The days on which continued fevers are said more particularly to subside, are the third, fifth, seventh, ninth, eleventh, fourteenth, seventeenth, and twentieth. De Haen collected from the writings which have been supposed to be the productions of Hippocrates, the results of the termination of one hundred and sixty-three cases of fever. Of these it is asserted that more than two-thirds terminated on one or other of the eight days above-mentioned; none occurred on the second or thirteenth day, and only one-third of the whole terminated on the eighth, tenth, twelfth, fifteenth, sixteenth, eighteenth, and nineteenth days.

Of one thousand seven hundred and seventy-three cases of which an account of the days of decline was kept by Dr. Stoker, two hundred and sixty-two occurred on the seventh day, two hundred and twelve on the ninth, one hundred and seventy-three on the eighth; on the fifth, sixth, tenth, eleventh, and twelfth, nearly an equal number, (about one hundred and twenty;) from the thirteenth to the thirty-first days, the number pretty uniformly decreases from eighty-two to two.

From the difficulty of ascertaining the actual commencement and decline of the symptoms

of fever with accuracy, besides that the disease is more protracted in its duration at some periods than at others, we are not inclined to consider these observations of much practical value.

Not only did the ancients suppose that fever terminated at certain determinate periods, but Galen affirmed that, after careful observation, he had been able to discriminate those days on which fever terminated favourably or unfavourably. Thus he asserted that the majority of fevers terminated favourably on the seventh day, a large proportion on the fourteenth; next in order he placed the ninth, the eleventh, the twentieth, or twenty-first, the seventeenth, the fifteenth, the fourteenth, the third, the eighteenth, the twenty-seventh or twenty-eighth. The sixth day, according to Galen, was always most unfavourable, fevers which terminated on this day being either in general fatal, the crisis imperfect, or the patient liable to relapse. Other unfavourable critical days were the eighth, the tenth, the twelfth, the sixteenth, and the nineteenth. The thirteenth was regarded as neither favourable nor unfavourable.

We do not enter into these details of supposed critical days, with the most distant wish to perpetuate what certainly appears a fiction, but to endeavour to guard the inexperienced against doctrines which deserve notice only from their antiquity.

It should be remembered that we have no grounds for ascertaining how time was calculated in those early days; besides the difficulty of ascertaining the precise hour or period of invasion, and the time occupied by the gradual and often imperceptible changes which announce the crisis. We know also that the duration of fever varies according to climate and the particular character of the epidemic: besides, we have endeavoured to shew that there are, comparatively, very few cases of fever in which some local inflammation does not exist at the beginning, or arise at some period of its progress, and which most materially interferes with any supposed regular duration.

It must be apparent, also, that the symptoms of fever may be not only mitigated, but their duration shortened, according to the treatment which has been adopted: indeed, fever is often rendered exceedingly tedious, either from neglect in its early stage, or from the sufferer being placed under circumstances which preclude the possibility of those means being applied which are most effectual in checking the progress of the disease.

These remarks are intended to apply to the various forms of continued fever. We admit that in periodic fevers the symptoms have a certain duration, and that in the eruptive fevers, (small pox, measles, and scarlatina,) the symptoms have also a fixed period of cessation or decline, unless their regular course be interrupted by the supervision of some local affection, or some peculiarities in the epidemic itself. These circumstances certainly, at first sight, give countenance to the doctrines we

are now impugning; but when we consider the many circumstances in which eruptive fevers differ from every other form of acute disease, their almost invariably fixed duration cannot be adduced as an argument in favour of the doctrine of critical days in continued fever.

Prognosis.—Although a considerable proportion of cases of fever recover, it is to be regarded as a dangerous disease. For the first few days its character may be mild, but symptoms often arise in its progress which place the patient unexpectedly in danger; while, on the other hand, the patient may recover from a combination of the most unfavourable circumstances.

In the first place, the prognosis will depend on the type of the fever, and the complications which arise in its progress. Simple fever, being the mildest, is the least dangerous form; indeed it seldom proves fatal, unless from the supervision of some local inflammation. Of the probable issue of complicated fevers, it may be said that this depends both on the importance of the organ affected, and the intensity or degree of the local disease. Cerebral is more dangerous than pulmonary or abdominal inflammation; and the various intestinal lesions are more dangerous than any form of pulmonic affection. If there be local disease in more than one organ, the prognosis must of course be less favourable than when the affection is confined to a single organ.

Of the prognosis of typhous fever, it may be stated that it is the most dangerous form of fever. Its fatality is materially influenced by the symptoms which arise, by the character of the prevailing epidemic, and the mode of treatment pursued. Indeed, every species of fever varies in severity in particular years, and even in particular periods of the same year. It is not easy to account for such variation in epidemics, nothing beyond the fact having been hitherto ascertained.

In the second place, the prognosis will also, in some degree, be influenced by the age of the individual. It is more fatal at some periods of life than at others. The following table will give a comparative view of the mortality of fever at different ages. It is abstracted from the records of the London Fever Hospital.

In the third place, the constitutional powers and previous habits of the individual will also materially influence the probable result of the case. Persons of a robust vigorous frame and sanguine temperament in general pass through fever better than those of a melancholic temperament and feeble powers; and those who have led a temperate life are more likely to escape the ravages of fever than such as have impaired their constitution by intemperance and excess.

In the fourth place, particular symptoms indicate a favourable or unfavourable prognosis. In acute diseases, and more especially in fevers, it is of great consequence to examine into the various conditions of the pulse. In fever we are to be guided chiefly by its frequency and volume. If it do not exceed 100 or 110 at any period of the twenty-four hours; if it be at the same time soft though not very compressible, and if the pulsations be regular, the indication, so far as the circulation is concerned, may be considered favourable.

The state of the respiration is also to be considered. If it be of natural frequency, or only a little accelerated towards evening, or at those periods of the day when an accession of fever comes on, resuming its natural state when the exacerbation abates, and is not attended with cough, it is favourable. Auscultation generally indicates the presence or absence of pulmonary disease; and as we have already seen that latent pulmonary affections may be going on without any external signs—cough or alteration in the respiration—frequent examinations of the chest by the stethoscope should be made.

In detailing the symptoms and explaining the causes of fever, we have seen the prominent importance of the nervous system: its condition, therefore, must in every instance materially influence the prognosis. If the headach, or giddiness, which almost invariably accompany the disease, continue moderate, or when in its progress they have become severe, but have yielded to appropriate measures—when moderate delirium does not come on till towards the middle of the second week of the disease, and appears chiefly towards the evening—when the patient enjoys intervals of refreshing sleep—or, if the sleep be protracted, he be easily roused from his slumber—if with these symptoms the state of the eyes and expression of the countenance be natural—or should moderate deafness without pain in the region of the ear supervene, a favourable result may be anticipated.

In no disease does the appearance of the tongue afford more satisfactory information than in fever. If, after it has been covered with thick moist fur, it appear cleaner at the edges, or after having been dry and parched, it become clean and moist round the margin, it is a favourable circumstance—more particularly if this change be accompanied with desire for food and abatement of the thirst, heat of skin, and other symptoms.

Another favourable symptom is the appearance of a warm general perspiration: it must, however, be distinguished from a cold,

clammy, or partial sweat, or from that occasioned by external heat.

A moderate spontaneous diarrhoea is often a salutary crisis of fever, and if it do not prove exhausting, should not be interfered with.

The prognosis may in some measure be formed from the posture of the patient. When an individual labouring under fever is able to change his position, and to retain it for any length of time, it is a favourable circumstance, shewing that a degree of muscular vigour still remains, and that the powers are not unduly exhausted.

The state of the blood, should there arise necessity for venesection, affords an important indication: if it flow readily when the vein is opened, and if on cooling the coagulum be firm and abundant, it is favourable, shewing that the system is in a vigorous state.

The unfavourable symptoms of fever may be classed under two conditions—those of undue or excessive excitement, and those of failure of the vital powers.

Under the first may be classed those symptoms which characterise great febrile excitement, more particularly violent action of the heart and arteries, pungent heat of skin, hurried breathing, headach, excessive thirst, and general functional disturbance. These symptoms are more particularly observed in the fevers of warm climates, in which all acute disorders run a rapid course, and are often very fatal. In such cases the excitement may be general, without any marked disturbance in any organ; and although this general excitement has been known in some instances to prove fatal without inducing any inflammatory complication, more commonly some organ becomes, sooner or later, inflamed, and according to the extent of the lesion produced, the danger of the patient is to be estimated.

When symptoms denoting inflammation of the brain come on, viz. acute pain in the head, delirium, suffusion of the eyes, throbbing of the carotid and temporal arteries, rolling of the head from side to side on the pillow, drowsiness or coma, the prognosis is unfavourable, especially if such symptoms occur in an enfeebled constitution, which forbids the adoption of such active measures as are necessary to subdue the local disease.

Again, if inflammation of the lungs or pleura, or of any of the abdominal organs, supervene, the particular lesion being recognized by particular symptoms, the prognosis is unfavourable, unless the local affection be speedily arrested. The safety of the individual in all such cases depends on the promptitude and judgment with which the treatment is pursued, and on the powers of the patient being adequate to contend with the disease and the treatment it requires.

The prognosis, however, is not to be deduced from general symptoms alone, but in connexion with the condition of the vital functions. Hence an unfavourable prognosis may be drawn from the following circumstances.

Extreme frequency and feebleness of the pulsations, exceeding 120 in the minute, indicate danger; when they exceed 130, the case may be considered nearly hopeless. Intermission or irregularity of the pulse is also a bad symptom. This state of the pulse no doubt depends on spasmodic action of the muscular structure of the heart, arising from the same causes which induce muscular tremor and subsultus tendinum, as we have observed irregularity or intermission of the pulse accompany the general muscular affection, and subside at the same time under a cordial plan of treatment and opiates. On the other hand, it may happen that fever has supervened on some organic disease of the heart which has given rise to the irregular action: these cases can only be ascertained by stethoscopic examination and the previous history.

The condition of the brain in fever affords many indications both favourable and unfavourable. We have already adverted to those symptoms which may be regarded as favourable. Of those which are dangerous, we may mention early delirium, which, although by no means a fatal, is always an unfavourable symptom. Coma indicates great danger. Muscular tremor of the hands, tremulous motion of, or inability to thrust out, the tongue, starting of the tendons, spasm of the diaphragm indicated by hiccup, great failure of muscular power, so that the patient cannot sustain his position on either side, but lies on his back sunk in the bed; involuntary evacuation of the urine and stools; or the opposite condition—retention of urine and difficulty of swallowing, indicate much danger.

Though the low or typhoid fevers are generally accompanied with symptoms of impaired energy in the brain, it should be kept in mind that subacute cerebral inflammation sometimes supervenes under circumstances of great general debility. Such a combination generally proves embarrassing, the practitioner having to contend with inflammatory symptoms, while the general powers are enfeebled and exhausted, or, as Dr. Bateman remarks, "the nature of the one affection absolutely contra-indicating the treatment, which the nature of the other as decidedly requires." When convulsions occur (which they do rarely) they always indicate speedy dissolution.

Loss of sight, although it seldom occurs, is invariably a fatal symptom. Partial paralysis of the retina, indicated by the appearance of black spots, called *muscæ volitantes*, floating before the eyes, picking at the bed-clothes—or endeavouring to catch or drive away imaginary objects—closure of the upper eyelid, which arises from debility of the levator palpebræ superioris; or the patient going to sleep with the eyelids half closed, may be regarded as alarming if not fatal signs.

Dropping of the lower jaw, so that the patient lies with his mouth open, the jaw-bone falling down from its own weight, in consequence of paralysis of the temporal and masseter muscles—grinding the teeth, which is

produced by spasmodic affection of the muscles of the lower jaw, denote great danger.

Another set of unfavourable symptoms which may be referred to the disorder in the brain, are great restlessness, tossing the arms about, and uncovering the body, though the skin be cool.

Any remarkable deviation from the natural state of the respiration or voice in fever is always to be considered unfavourable. The alteration in the tone or strength of the voice, not depending on the dry state of the mouth, throat, teeth, and lips, which prevents the free use of the organs of speech, arises from loss of power in the muscles of the larynx. When the breathing is hurried without any corresponding disease in the respiratory organs, it is a bad omen, shewing that there is great debility. When there is intense pulmonary inflammation, either bronchitis, pneumonia, or pleurisy, there is considerable danger. That form of pulmonary disease to which the French writers have given the term *latent bronchitis* is always a dangerous and often fatal complication. It is not indicated by any pathognomic symptom, and is only detected by auscultation; and when it occupies both lungs, it speedily destroys the patient. The obscurity of pulmonary disease in fever is often owing to the condition of the brain, and hence the indispensable necessity of the frequent application of the stethoscope in the progress of fever.

The symptoms in the alimentary canal which give an unfavourable aspect, are fiery redness of the tongue, its middle or root, as well as the teeth, being covered with dry, black sordes; or a preternaturally clean, red, dry, or fissured tongue—tympanitic distension of the belly, with or without pain on pressure—exhausting diarrhoea, the evacuations, consisting of light yellow, serous fluid, being passed unconsciously—hemorrhage from the bowels or bladder. These symptoms are always of themselves exceedingly unfavourable, as they indicate severe lesion of the mucous membrane of the intestines, and when accompanied with sympathetic sensorial disturbance, the issue of the case is seldom doubtful.

Another very alarming and always fatal symptom is sudden acute pain in the abdomen, followed by vomiting, rapid distension, collapse of the features, and extremely small, quick pulse. The pain at first is confined to a limited space, but it soon becomes diffused over the abdomen. These symptoms indicate intestinal perforation, which, it is unnecessary to add, is always a fatal event.

There are certain external symptoms in fever which assist the physician in determining the probable issue.

The expression of the countenance always affords an indication of much value; so much so that those who are familiar with the disease can often pronounce with great accuracy as to the condition of the patient from attentive observation of the countenance alone. It is difficult, if not impossible, to describe the various changes in the countenance in fever: they are known only to those who

have had much experience in this disease ; and a knowledge of them can only be acquired at the bed-side. In mild cases, there is little alteration from its natural aspect, and should any circumstances arise in the progress of fever sufficient to produce change in its expression, a sure indication of amendment is improvement in the expression of the countenance.

In almost every instance patients become thin under fever ; and unless the emaciation be excessive, it is a more favourable symptom than when there is comparatively little wasting of the flesh. When the patient emaciates rapidly, so that he becomes almost a living skeleton, it is generally owing to lesion of some internal organ, very often of ulceration in the bowels. In these cases the prognosis is unfavourable.

We have already alluded to the fetor of the body in some forms of fever. This sometimes arises from inattention to cleanliness when the patient passes his evacuations unconsciously, but more commonly from a vitiated state of the secretions, and consequently of the perspiration. It is always a bad symptom.

Exudation of blood from the vessels of the skin giving rise to petechiæ, or vibices, is an unfavourable symptom, shewing great general debility and relaxation of the capillaries, the blood being at the same time deficient in fibrin. Huxham observes,* " that when black, livid, dun, or greenish spots appear, no one doubts their malignity ; the more florid, however, the spots are, the less is to be feared : it is a good sign when the black or violet petechiæ become of a brighter colour. The large black or livid spots are almost always attended with profuse hemorrhagies. The small dusky brown spots, like freckles, are not much less dangerous than the livid and black, though fluxes of blood do but seldom accompany them. The vibices, or large livid or dark greenish marks, seldom appear till very near the fatal period."

When parts which are subjected to pressure shew a tendency to gangrene, it is an unfavourable sign : in some cases large sloughs form on the sacrum or hips, and produce so much constitutional irritation as ultimately to destroy life. Coldness of the extremities, denoting failure in the nervous energy, though often observed two or three days before the patient dies, indicates the near approach of death. The same indication may be taken from cold sweats, which are also referable to failure of the circulation and relaxation of the capillaries. When the extremities become cold, the surface bedewed with a cold, clammy sweat, the countenance collapsed, the respiration short, interrupted, or laborious, the fatal issue is not far distant.

Causes of Continued Fever.—It has been well remarked by Dr. John Hunter, in his work on the Diseases of the Army in Jamaica, that the great improvements to be made are not so much in the cure as in the prevention of dis-

eases, which depends altogether upon the knowledge of their causes.

The causes of fever have been usually considered under two divisions. The first comprehends those circumstances which predispose to, or render the body susceptible of the operation of the causes which produce the disease : they are termed *predisposing*. The second includes such causes as immediately excite the fever, and are consequently called *exciting*.

1. *Predisposing causes.*—From this distinction it may appear that a certain predisposition is necessary before the exciting causes can produce their effect ; or, in other words, that a predisposition must exist, or be engendered before symptoms of fever can be established. Although a certain condition of the system renders the operation of the exciting causes more efficient, and in some cases contributes essentially to bring on the disease, the exciting causes frequently operate, without the intervention of the predisposing. It has not unfrequently happened that individuals in perfect health, on being exposed to infection, have almost immediately been seized with fever.

A woman admitted into the fever-wards of the Whitworth Hospital stated that on a certain day (Wednesday) preceding the day of her admission, a person not yet recovered from fever came into the house where she then was, and sat down close beside her. She became immediately sensible of a heavy, disgusting odour arising from the person of this individual ; was instantly affected with headach and became very weak ; and on the same evening, long-continued rigors, followed by heat and perspiration, came on. She afterwards passed through a severe form of fever.

A clergyman, having enjoyed during the morning his usual health, and having performed the customary church-service of the day, visited, before dinner, a small parochial fever hospital. While speaking to a woman recovered from fever, he discovered he was standing on straw just removed from the bed of a fever-patient, in which there was much feculent matter. The odour from thence struck him with force ; he immediately felt pain in his head, sickness, and prostration. The same evening he shivered, and fever of unusual severity ensued. Though little hopes were at one time entertained of him, he ultimately recovered.*

A child, on being discharged from a fever hospital, was admitted into a charitable institution, and brought with her a small bundle of clothes which had not been disinfected. The bundle was opened by a woman resident in the institution, who perceived an extraordinary disagreeable odour to issue from it. In a few minutes the woman became ill, felt sick at her stomach, and afterwards passed through fever.†

Nurses, too, have become so powerfully affected on removing the evacuations of a

* Marsh on the Origin of Fever, *Dubl. Hosp. Rep.* vol. iv.

† Barker and Cheyne's Reports, vol. i. p. 472.

* On Fever, chap. viii.

fever-patient, or from applying dressings to gangrenous sores, as to sicken with fever almost immediately after. Instances of this kind are familiar to the writer, and have no doubt been often remarked by other physicians.

It has been confirmed by experience, however, that when the system is in full health and vigour—when all its functions are duly performed and nicely balanced, it is enabled to resist any powerful morbid impression. As soon as this equilibrium is disturbed—when the powers are enfeebled from any cause which tends to break up the strength, or to destroy that harmony of relation which constitutes health, the same causes which were formerly innocuous, become powerful agents in the production of disease. It is on this principle that attendants on fever patients are enabled to resist infection so long as they continue in full health. Hence an important practical principle is deduced, that those who are engaged in attendance on fever should not approach the sick while any symptoms of even slight indisposition are felt.

In all the instances of medical practitioners who have become the subjects of fever, which have come under our notice, there have been almost uniformly, for some time previous to the origin of the disease, evident signs of disordered health. It very generally happens that when precursory symptoms of fever appear, the struggle made against its insidious approach too often renders the subsequent progress formidable, while under early judicious management the primary symptoms might have soon subsided.

It may be useful to point out a few of the more striking and important circumstances which render the system susceptible of the influence of the exciting causes of fever. The first to be noticed is the particular period of life at which fever most frequently occurs. That some idea may be formed of the comparative frequency of fever at different ages, the following table has been constructed from the register of patients admitted into the London Fever Hospital during one year.

Under 10 years	18
Between 10 and 15	68
15 and 20	130
20 and 25	178
25 and 30	100
30 and 35	44
35 and 40	44
40 and 45	31
45 and 50	14
50 and 55	10
55 and 60	8
60 and 65	8
65 and 70	2
70 and 75	3
75 and 80	1
Ages not ascertained....	17
324 males }	
352 females }	..Total.. 676

From this abstract it appears that fever is most common between the ages of twenty and twenty-five, and next between fifteen and twenty. It decreases in frequency from the age of puberty downwards; and as a general rule it may be affirmed that children, and particularly infants, are peculiarly exempt from the exciting causes of idiopathic fever—the febrile ailments to which they are subject being almost invariably symptomatic of some local disturbance, such as dentition and disorder of the bowels. The frequency of fever between the ages of fifteen and thirty may be explained by the development which takes place and the tendency to plethora in young persons. It may also be stated that the type of fever is apparently influenced by the particular period of life—inflammatory or acute fevers being more common from puberty to the age of forty. It is also modified by individual temperament, persons of the sanguine being most liable to the acute, those of the melancholic to the low forms of the disease.

We have already noticed how much a vigorous state of health contributes to protect the system against the influence of the exciting causes of fever: it consequently follows that whatever tends to impair the health becomes indirectly a predisposing cause. Those circumstances which induce plethora on the one hand, or inanition on the other, may therefore be regarded both as predisposing and exciting causes, according to the duration of their application and the condition of the system at the time they are applied. Of the two, however, scarcity or famine is the most powerful: indeed, in all ages famine and disease have been observed to be co-existent. Hence it may be considered as an axiom, that scarcity of food, as well as food of a bad quality or improper kind, powerfully predisposes the system to the influence of the exciting causes of fever.

In tracing the records of epidemics, it will be found that they have almost invariably been preceded or accompanied by distress among the lower orders, either from the high price of provisions, or from some commercial causes, throwing the manufacturing portion of the community out of employment. In the epidemic fever which has at various times visited Ireland, all the medical practitioners allude to the inadequate supply of food among the inhabitants of the towns or districts where it raged. Insufficient and unwholesome nutriment, by impoverishing the blood, not only brings on emaciation, but depresses the nervous energy; hence the system, under such circumstances, is readily acted on by the exciting causes of fever. In times of pestilence, therefore, due attention should be paid to the quality as well as quantity of the food, avoiding on the one hand too scanty an allowance, while on the other, the stomach should not be overloaded, especially with stimulating food. We consider a moderate but liberal allowance of animal food to be a good preservative against the exciting causes of fever. This observation is

strengthened by the fact, that during the plague, which raged in London in the seventeenth century, the butchers of the metropolis were observed to be remarkably exempt from the disease, and in our own experience butchers are rarely the subjects of fever.

The moderate use of wine, by strengthening the body, obviates a predisposition to fever, and therefore, during the prevalence of epidemic fever, has been recommended. It should, however, be strongly impressed on the mind, that the immoderate use of wine or intoxicating liquors, under such circumstances, actually renders the body more susceptible of the exciting causes. Dr. Chisholm remarks that those who were addicted to intemperance, were most subject to the fever of Grenada; and as every kind of ardent spirits operates as a slow but sure poison, producing great debility, and sapping the powers of the system, it is the duty of every one to discourage their use in the time of epidemic visitations.

Bodily fatigue may be mentioned among the causes which tend to impair the natural vigour of the body, and thus render the system more susceptible of the exciting causes of fever. This may be either excessive and of short duration, as in violent exertion, or it may be prolonged, as in long journeys. It is well known to army surgeons, that soldiers very readily fall into fever, when exposed to its causes, after a long march or severe and continued exertion in the field; and, in times of scarcity and privation, the journeys which whole families are not unfrequently compelled to take in quest of employment and support, render them more liable to be attacked with fever than they otherwise would be.

Another set of predisposing causes are those which give a severe shock to the nervous system. The various kinds of mental emotion—fear, grief, anxiety, disappointments, long continued watching on a sick bed, intense study, want of sleep, may individually be ranked among the predisposing causes of fever. As Dr. W. Philip observes, therefore, few things are better preservatives against infection than fortitude and equanimity. Nothing, we are informed by those who voluntarily exposed themselves to the contagion of the most pestilential fevers, was found so great a preservative against its effects, as a steady adherence to what they believed their duty, banishing from their minds, as much as possible, all thoughts of danger, and avoiding every kind of passion, particularly the depressing passions. Every body knows how much fear predisposes to infection: on this account it is of consequence to strengthen the faith of the ignorant in the efficacy of any thing they believe capable of preserving against infection.*

2. *Exciting causes.*—The *exciting* causes of fever form a most important and interesting subject of investigation, though it must be acknowledged that notwithstanding all that has

been done in this department of etiology, the subject is still involved in obscurity.

There can be little doubt that the opinion, entertained by many, of the exclusive origin of all forms of continued fever in contagion, has tended much to limit our knowledge of its other causes. That fever does occasionally originate in contagion few persons of experience or unbiassed judgement will now deny; but there are other causes which operate with equal certainty, a knowledge of which it is exceedingly important to attain.

The records of medicine contain abundant proofs of the origin of fever in the poison generated by the decomposition of vegetable and animal matters, though it seems probable from some facts, that the exhalation from vegetable substances in a state of putrefaction is more injurious than that from animals; and from the circumstance of the prevalence of fever in some particular places, and the number of persons who have become affected from residence, even for a short time, in those situations where it has been found to prevail, it has been concluded that fever may arise from a terrestrial or atmospheric poison generated in such localities. To the febrile poison however produced, the term *miasm*, (from the Greek word importing pollution, corruption, or defilement generally,) or *malaria* (from the Italian term implying bad or impure air,) has been applied. It is well ascertained that vegetable as well as animal substances, in a state of decomposition, emit effluvia or exhalations which prove extremely hurtful to the human body, and when applied in a state of sufficient concentration are productive of most severe illness, or even of instantaneous death. On this account, all febrile poisons have been supposed to originate in one or other of these sources, or in a peculiar unknown pestilential condition of the atmosphere, to which, from the number of persons simultaneously affected, the term *epidemic* has been given.

We know very little about the physical qualities of these emanations or vapours beyond their noxious effects on the animal body: they are invisible and without taste or smell: chemistry has failed to unfold their nature, as on submitting them to the test of chemical analysis, nothing beyond the fact that they contain a considerable proportion of hydrogen and carbonic acid gas has been discovered. Hence some ingenious persons have endeavoured to deduce the unhealthiness of low damp situations in the warm season, to a supposed deficiency of oxygen in the atmosphere, though, as Dr. Bancroft has very justly stated, were we to assume this principle, fever should be produced by every crowded assembly, and in a multitude of situations where no such effects have been observed.

It would appear from fever arising in particular localities, that noxious exhalations are generated from some soils only, and that the combination of heat and moisture is also necessary for their production. We find, accordingly, that in the same district, one place

* On Febrile Diseases.

or spot is unhealthy, while at a very short distance, perhaps, the inhabitants are remarkably free from disease; and that, in some seasons which have been remarkably dry, even when the heat has been unusually great, fever is either little prevalent, or entirely unknown.

Though every soil contains an admixture of animal matters in a state of decomposition, it is probable that the deleterious principle which gives rise to fever is derived from vegetable substances almost exclusively. This opinion is strengthened, if not confirmed, by what is observed to take place during the process of preparing hemp, flax, and indigo for the various purposes for which they are used in commerce.

These plants in their preparation are steeped in water, and during their decomposition extremely offensive emanations arise. Lancisi gives the history of an epidemic fever, which for several summers infested and almost depopulated a town situated in an elevated and salubrious part of Etruria. This fever arose from the emanations from ponds or stagnant waters in the lower part of the town in which hemp and flax were macerated: on the process being afterwards prohibited, there was no recurrence of fever. Dr. Bancroft states he was informed at Naples that in several places near that city, and particularly in some beyond the Grotto of Posilippo, sleeping in houses contiguous to ditches in which hemp or flax were macerating had been almost constantly followed by fever. Similar effects have been observed from the fermentation which the indigo plant undergoes in the process for extracting the colouring matter. It appears that, after the extraction of the dye, large heaps of the plant are formed near the manufactories and houses of the work people, for the purpose of undergoing decomposition so as to form manure. After being frequently moistened by the heavy rains, and heated by the rays of a scorching sun, copious exhalation takes place from these beds of putrifying vegetable matters, in consequence of which the workmen, and persons who live near, were constantly attacked with dangerous fevers. This circumstance having of late years attracted the attention of the indigo planters, the plant, after the extraction of the dye, is not permitted to be formed into heaps near the works or dwellings of the labourers. Fevers are consequently now comparatively rare among the workmen.*

From these facts it would appear that there are some deleterious emanations emitted during the putrefactive process of vegetable matters. Some have endeavoured to shew, however, that moisture alone, applied to the living body, produces fever. This position has been again and again disproved by the most conclusive facts; indeed, the argument adduced by Dr. Bancroft, of the remarkable healthiness of the men employed in the Newfoundland fisheries, where they are generally enveloped in the dampest fogs for several months together,

affords the least ambiguous proof, that the atmosphere when loaded with moisture only, has no greater power in causing fever, than it has when in any usual state of dryness.

It would appear that a combination of circumstances, more particularly heat and moisture, is necessary to give potency to putrid emanations.

Miasmata generate very slowly in a perfectly dry situation; and it has been generally remarked that fevers are not prevalent in dry seasons. Dr. Bancroft states that it is found on the west coast of Africa, and in some of the West India islands which are liable to long droughts, as Barbadoes, and more particularly Antigua, that marsh fevers occur very seldom in dry seasons; but that they become every prevalent whenever these droughts are suddenly terminated by frequent rains.

Dr. James Clark, in his Treatise on the Yellow Fever, observes that when there was much rain in the months of May and June, and dry sultry weather prevailed in the following months of July and August, fever raged much among the troops and strangers. This is precisely what is observed to take place in the fevers of temperate countries.

The effect of heat in promoting putrefaction, and the consequent generation of emanations, is evident from the variation observed in the putrefactive process in different temperatures. A very low or a very high temperature is unfavourable to the decomposition of dead inorganic matter, putrefaction being entirely suspended at the freezing point, and proceeding very slowly at any degree under 45° of Fahrenheit: it gradually increases from this point, and appears to take place most readily about 100°, but to be checked when the temperature exceeds 100°. It has been remarked that in districts where marsh fevers are prevalent, their progress is arrested, and in many places they entirely disappear during a continued frost: when spring advances they reappear in a mild form; in summer they prevail more extensively; and in autumn the cases not only increase in number, but assume a more severe form. Precisely the same thing happens with regard to the continued fevers of temperate countries, so that the combination of heat with moisture must be admitted to be a powerful circumstance in the production of fever.

It is necessary, however, to state that paludal emanations are generated in greater quantity, and probably in a state of greater concentration, when there is only such a degree of moisture as facilitates putrefaction.

It is well known, that in marshy districts fevers do not appear in the rainy season till the water has nearly evaporated or drained off; and, as Dr. Bancroft states, attention to this important fact will enable us to understand, why in some countries frequent and heavy rains render marsh fevers prevalent, while in others the deprivation of rain for two or three months produces equally morbid effects.

The fact that in very dry seasons fevers are seldom observed has been already noticed; in

* Bancroft on Yellow Fever.

very low situations, where the ground is much moistened and often inundated in the rainy seasons, the inhabitants remain free from fever till the water evaporates from the heat of the weather so as to leave the ground in many places uncovered. The comparative insalubrity of situations in the vicinity of stagnant waters compared with running streams is thus explained.

In the third volume of the *Journal de Physiologie*, an interesting account is given of a fever which occurred in the autumn of 1822; its origin was ascribed to exposure to the emanations of stagnant waters, and using the same water in food. The symptoms of the fever were pain in the epigastrium, purging, distention of the belly, feeble pulse, thirst, black furred tongue, fetid sweats, and great prostration. The convalescence was remarkably tedious. Hence the expediency of occasionally inundating a marsh in hot weather, when any deleterious exhalation arises.

There is considerable difference in the various kinds of soil as regards the generation of emanations. Fevers have been generally remarked to be more common when clay constitutes a considerable proportion of the soil. Whether this is owing to the greater humidity of a clayey soil, or whether it favours the putrefactive process more than other kinds, is yet a matter of conjecture.

We may here allude to the singular exemption of persons who live near peat-bogs or moors from marsh fevers; this has been observed to be remarkably the case in some districts of Scotland and Ireland. The cause of this apparent salubrity in the districts referred to has not been satisfactorily explained, but it is well known that peat-bogs have the remarkable property of preserving both dead animal and vegetable matter from putrefaction. According to Dr. Bancroft, not only plants and trees, but even human bodies with their clothing, when completely immured in the peat soil, will scarcely undergo any change during a long course of years; and it is probably owing to this peculiar property that they do not exhale, and perhaps do not generate, miasmata similar to those which arise from marshes. Some chemists who have made experiments with a view to discover the nature of peat, are of opinion that its antiseptic powers are derived from *tannin*, though from a certain quantity of iron being always found in peat, it is probable that this metal may have a considerable share in contributing towards its antiseptic properties.

From what has been stated, it is evident that not only the origin but the propagation of fever depends on a great variety of circumstances, which, in tracing the causes of the disease in any particular locality, should be minutely investigated.

It is often found that fever is confined to a limited district, so that one part of a town is sickly while other districts are healthy. This has been repeatedly remarked in the malarian fever which prevails in the summer and

autumn at Rome, the disease appearing chiefly in the low parts of the city near the river, while the other districts are quite free, unless when the wind blows in the direction of the Pontine Marshes. Particular streets have been observed to be more unhealthy than others; and it has been said that fever has run through every house on one side of the street, while the inhabitants of the opposite side escaped.

Ample proofs of the injurious effects of emanations from vegetable substances in a state of putrefaction on the living body having been adduced, let us next examine into those arising from the decomposition of animal matter. It would appear, however, from the immunity of persons exposed to the effluvia of dead animal matter, that its application to the living system is rarely followed by any injurious consequence. Persons who are much exposed to animal putrefaction, such as the men who are employed in particular trades, skimmers, parchment-makers, catgut and glue-makers, nightmen, and students of anatomy who are engaged for several hours daily in prosecuting their anatomical studies, are seldom known to suffer from their occupation. The same immunity is not enjoyed by persons who are long enough exposed to the effluvia from putrid vegetable substances. It is true that persons who have been engaged in the removal of corpses from burying-grounds, and nightmen, have suffered from their occupation; but the disease occasionally induced in them does not appear to have any resemblance to fever.

Fourcroy states that in some of the burial-grounds of France, when the grave-diggers in opening the ground penetrate graves in which bodies have been recently placed, they become affected with vertigo, sickness, tremors, and a feeling of oppression; in some instances they become asphyxiated: it has also been observed that numbers of those who live in the vicinity of cemeteries labour under dejected spirits, sallow countenances, and febrile emaciation.

The human body, not only when affected with disease, but under certain circumstances in a state of health, generates a poison which gives rise to fever. This principle, notwithstanding the reasoning of ingenious disputants, has been incontrovertibly established by a multiplicity of facts.

There can be no doubt that the most potent febrile poisons are the exhalations from the bodies of persons labouring under some form of fever. The proofs on this point are so clear and satisfactory, that few persons deny that fever originates in contagion. To assert that contagion is the only principle capable of producing the disease evinces a very limited notion of the circumstances under which fever is generated; and yet this opinion was taught by Cullen, and is implicitly believed by many even in the present day. It is almost as absurd as the idea still entertained that fever cannot be propagated by contagion. Sir John Pringle states that he has observed the hospitals of an army, not only

when crowded with sick, but at any time when the air is confined, and especially in hot weather, produce fever of a peculiar kind which is often mortal. The same thing has been observed in almost every hospital, and shows that the congregation of sick persons does, under some circumstances, produce fever.

It is not necessary however that such exhalations, in order to generate fever, should arise from the bodies of persons in a state of disease: it is well known that fever is readily produced by the accumulated emanations of healthy persons. Sir John Pringle mentions that he had observed fever arise in full and crowded barracks, and in transport-ships when filled beyond a due number, and detained by contrary winds, or when the men had been long kept at sea under close hatches in stormy weather.

We have frequently observed that the febrile poison becomes so virulent in a confined atmosphere, that every person who has been exposed to its influence has been attacked with fever; and as if to show the agency of a specific poison, the symptoms in every individual who has received the infection have been remarkably similar.

It is this concentration of human effluvia which is so productive of fever in crowded ships, prisons, and workhouses, more particularly in warm weather, and when little attention is paid to ventilation; for it should be remembered that the febrile poison may be so diluted by pure air as to be rendered almost innoxious. Few parish workhouses, when overcrowded with paupers, especially in the summer months, escape the visitation of fever; and when an epidemic appears in a large town or manufacturing district, the ravages which it commits in the crowded ill-ventilated dwellings of the poor are often appalling.

The facts which have been accumulated from the most authentic sources prove that fever may be communicated from person to person by contagion. It does not require actual contact to produce the disease; exposure to the atmosphere of the apartment, but more especially to the exhalation from the body of a fever patient, being sufficient. In the article *CONTAGION*, (to which we refer for more ample details,) such abundant illustrations have been brought forward, that the most sceptical must be convinced of the origin of fever in this source. We certainly think that Dr. Marsh, in his paper on the origin of fever,* has brought forward a body of evidence which should alone decide the question. The facts there collected are corroborated by the experience of every fever hospital as to the medical officers, nurses, and immediate attendants on the sick, and every inmate of the establishment, of whatever description, being with few exceptions affected with fever. We have known many instances of nurses pointing out the very patient from whom they received the infection; others have been sensible of a sudden and particular impression

at the moment the poison was received. This impression has been sometimes from the fetor of the body, not unfrequently from the stools, or in removing the linen of the patient.

Persons in a state of full health and vigour are much less likely to become affected with fever, than those whose powers are exhausted. It is on this principle that the nurses and attendants in fever hospitals resist for a time the febrile poison; but after a longer or shorter exposure, more especially if the strength has been impaired by bodily fatigue, want of sleep, and close confinement to the sick room, they almost invariably lapse into fever—a convincing proof that whatever weakens the general strength tends to render the operation of the exciting causes of fever more certain and effectual.

Any undue mental fatigue also powerfully aids the operation of the exciting causes of fever; and we have often verified the remark of Dr. Marsh, that in such cases the violence of the disease falls on the brain and nervous system, producing what is emphatically termed *brain fever*.

In the same manner we may explain satisfactorily the rapidity with which contagion spreads in times of scarcity or famine. The poor under such lamentable visitations are generally exposed to circumstances, which render them readily affected by causes which under more favourable events would be inoperative. Fatigue, exposure to cold and wet, insufficient or improper kind of food, are the too general attendants of epidemic fever among the poor.

Though mental emotion of a depressing kind powerfully predisposes the system to fever, it is singular how much an unusual degree of excitement acts apparently as a preventive. It is not unusual to observe that, during the painful anxiety and suspense, between hopes and fears as to the recovery of a valued relative and friend, the body is as it were armed against the effects of contagion. When this state of excitement is withdrawn, it is frequently followed by the same disease which was the cause of such intense anxiety, as if, in short, the system became relaxed so as to receive the influence of the infection to which it had been exposed.

From what has been stated, it is evident that when there is any indisposition, exposure to contagious fever should be avoided.

The means of guarding against contagion must at once suggest themselves. These consist in ventilation, separating the healthy from the sick, avoiding the effluvia from the skin, from the breath, and more especially from the evacuations; in adopting a nutritious but not stimulating diet; and in preserving moral courage,—fear, as we have stated, always predisposing the system to infection, so much so, that during the prevalence of an epidemic disease the terror it induces tends materially to increase the number of its victims.

The following brief sketch of fever originating in long-continued mental anxiety, by

* Dublin Hospital Reports.

Dr. Cheyne, vividly describes a not infrequent and somewhat peculiar form. "The *causes* are loss of property, of character; wounded pride. *Invasion* insidious, indistinct, patient generally unable to assign the date of the commencement of the attack; for some time before he has been complaining of bad nights, or has had symptoms of a common cold, which almost insensibly degenerate into the proper symptoms of fever; then, from an ignorance of the nature of his illness, he neglects himself, perhaps for many days; and at last when visited by a physician, he appears utterly unconscious of the formidable nature of his disease, and probably says he has no complaint—he is merely very weak: the symptoms are those of the typhus gravior of nosologists; a red suffusion of the eye; prostration of strength; subsultus tendinum; quick and weak pulse; hurried breathing; dun petechiæ, or a mottled or morbillary state of the surface. Of such patients a great proportion die. The most remarkable part of the disease is that it does not spread." Dr. Cheyne has no recollection of a second case of this kind of fever occurring in a family, and he has never been able to discover that the patient had been exposed to contagion. It would seem to arise solely from mental causes.*

Few circumstances connected with the causes of fever have attracted more attention than its tendency to become epidemic and to prove malignant and fatal at particular times, while at others the disease is little prevalent and of a mild character. These variations in febrile diseases have existed in all ages; they were particularly remarked by Hippocrates, who ascribed them to something divine, in which idea he was followed by Galen. In more modern times, these differences have been ascribed to the influence of some atmospheric or terrestrial agency, of which little or nothing is known except the effects it produces in the propagation and malignity of diseases. The notion that such pestiferous causes depend on planetary influence has been long exploded, though they appear to have an intimate connexion with sudden and extreme variations of temperature, more especially excessive heat combined with moisture. It is by no means uncommon to observe the prevalence of fever sensibly checked when the air is dry and cold.

Other contagious diseases as well as fever become epidemic and malignant at particular periods. This has been more especially observed with regard to small-pox, measles, and scarlatina, which, though never extinguished, are more frequent at some periods of the year, as well as more malignant at certain seasons than at others.

It is probable, therefore, that the circumstances which contribute to the prevalence as well as malignity of febrile diseases, operate by increasing the predisposition, or by rendering the body more susceptible of the influ-

ence of their various exciting causes. Hence the obvious effect of living in confined places, or of scarcity, or of any causes that undermine the powers of the system, in rendering the exciting causes of fever operative.

Not only is there a great difference in the number of persons affected with fever at particular times, but there is often, also, a remarkable similarity in the symptoms. Thus in the winter and spring months, the fever is of a more acute character, and generally complicated with cerebral or pulmonary inflammation. In the autumn, they are of a less active kind, and accompanied with more or less gastric irritation.

It is impossible, in the present state of our knowledge, to account for these various modifications in the character of fever, though it is of the greatest importance to observe them with the view of regulating the treatment.

Climate has an important influence, not only in giving a predisposition to fever, but in modifying its character or type. The inhabitants of warm climates are more liable to fever than those who reside in cold or temperate countries. The symptoms also are generally more violent, and the progress of the disease more rapid, while the type of the fever is very liable to change. The predisposition to fever, however, diminishes by continued exposure to its causes, and hence the immunity frequently observed in the natives of warm climates, while strangers or new comers are almost invariably attacked soon after their arrival, with the peculiar fever of the country.

We have already alluded to the effect of heat in the production of fever. The negative principle *cold* has been usually placed among the exciting causes. Though, undoubtedly, cases of mild fever may be traced to exposure to cold, it is more probable that it acts as a predisposing cause, especially when the body is weak, and little able to resist its effects. Dr. Marsh is of opinion that cold, like contagion, is an impression made on the sentient extremities of the nerves; its effects are in like manner instantaneous; its action, though powerful, is resisted when the body is vigorous and strong, but its impression upon those who are exhausted, fatigued, or relaxed, is followed very frequently by consequences formidable and even fatal.

It appears from some facts which have been noticed, that while some individuals are enabled to resist the operation of the exciting causes, others are only indisposed in a peculiar and indefinite manner after exposure to them, as if there were a struggle in the system to obviate their effects.

Fever, moreover, has been apparently induced by exposure to other acute diseases. Dr. Marsh mentions the case of a nurse in Stevens's Hospital, who was suddenly seized with illness while in the act of turning in the bed a boy labouring under confluent small-pox. She remained ill but not incapacitated for business for three days. She then had rigours followed by severe fever, the ordinary

* Marsh on the Origin of Fevers, Dub. Hosp. Rep.

typhus of this country. Dr. Johnson asserts that he observed in some instances that the ward-maids of the lying-in hospital caught typhous fever from the patients then affected with puerperal fever.

It would be exceedingly important if the mode in which the various febrile causes produce their effects could be satisfactorily demonstrated. It appears evident, from attentive observation of the general characters of fever, that there is occasionally a very remarkable difference in its forms or types, as well as in the particular symptoms on which its distinctive varieties have been founded.

The local lesions or complications, we have seen, assume remarkable variation in certain seasons and in particular epidemics, both in respect to the organs individually affected, and in the degree or intensity of such local inflammations. These circumstances lead to the belief, either that the febrile poison is different at different times, or that it is so modified by the state of the system as materially to alter its effects. The former is the more probable explanation, though from the nature of the febrile poison such difference cannot be demonstrated, but is only rendered probable from its effects on the human body.

Though it is impossible to explain the operation of all the exciting causes of fever, there appears to be a very close analogy in the action of many to that of other poisons. We know that this class of agents (poisons) affect different structures: the narcotics, for instance, act on one organ—the nervous system; others have a twofold action, as in the instance of the acro-narcotics, which evidently operate both on the nervous system and on the mucous membrane of the bowels, giving rise in the former to peculiar symptoms of narcotism, while a more severe effect is produced on the latter—inflammation and its consequences.

It cannot be demonstrated, but it seems more than probable, that some of the febrile poisons, whether originating in animal, vegetable, or atmospheric miasmata, operate on particular structures.

In some cases it would appear that the brain and nervous system are the only organs affected by the febrile poison; at all events, the nervous system appears to be early, if not primarily disturbed, as is evident from the shock which the whole system receives on exposure to some of the causes alluded to.

The symptoms in the brain are not, however, always the effect of the primary action of febrile causes on this organ. The nervous system is so susceptible of distant sympathetic impressions, that there is often great difficulty in distinguishing primary from secondary cerebral disease in fever. When there is intestinal affection more especially, the brain always sympathises; in which case it is often very difficult to determine whether the cerebral disturbance arise from the peculiar operation of the febrile poison on the nervous system, or whether it be only sympathetic of the morbid condition of the alimentary canal.

Again, fever assumes particular forms at different seasons of the year. It is well known that in some epidemics, and at certain seasons, the mucous membrane of the air-passages is affected, the existence of this form of fever being indicated by the catarrhal symptoms which accompany it. There seems every reason to believe, that at those periods when epidemic catarrh or influenza appeared, and of which Sydenham, Huxham, and Baker have given faithful and valuable reports, some peculiar condition of the atmosphere prevailed.

In like manner, in the autumnal months, the symptoms of gastric disorder form the prominent character of the fever. We have seen also that intestinal affections are not only more common at particular times, but occur in a larger proportion of cases in some localities than in others. This evidently arises from some circumstances peculiar to those situations. The effect of terrestrial emanations, rendered virulent by long-continued rains in hot climates, in producing dysentery, has been remarked by many writers and army-physicians.

We shall next consider how far morbid states of the blood are to be regarded as exciting causes of fever.

The ancient writers ascribed with great truth the origin of many diseases to a morbid condition of the blood and humours; and though the cultivation of anatomy has led to the investigation of the solids as the great source of diseases, yet that many arise from a morbid state of the blood is admitted even by the warmest adherents of solidism.

No one doubts that scurvy depends on vitiation of the blood in consequence of improper diet or living in an unwholesome atmosphere, and that in its progress (whatever cause may have produced the alteration in the blood) various local diseases take place; shewing, as Andral remarks, "that many lesions, apparently inflammatory, are far from depending simply on a local morbid state, but being connected with certain conditions of sanguification, can be removed only by a return of that process to its natural condition."

Sir John Pringle mentions a remarkable fact which came under his personal observation, of a person being seized with dysentery by making experiments upon human blood, which had become putrid by standing some months in a close phial.

M. Gendrin injected one ounce of blood, drawn from the veins of a patient labouring under putrid fever, into the cellular tissue of the groin of a cat. Copious vomiting, dyspnoea, small, frequent, irregular pulse, dry brown tongue, great prostration, and slight convulsions before death, were the effects which followed this experiment. The animal died within seven hours after the operation.

Duhamel has related the case of a butcher who suffered from a most malignant disease, and which proved fatal in four days, from putting into his mouth the knife he had employed in slaughtering an ox that had been

overdriven. An innkeeper wounded himself with a bone of the same ox in the palm of his hand; the arm mortified, and he died in seven days. In two women who had received some drops of the blood of the same animal, the one on her hand, the other on her cheek, the parts to which the blood was applied were seized with gangrenous inflammation.

It is well known that specific febrile diseases, small pox, and even measles, can be produced by inoculation; and that these diseases, as well as the syphilitic poison, may be communicated through the umbilical circulation from the mother to the fetus in utero, while a healthy infant after birth may become affected with syphilis from the diseased milk of an infected nurse. It has also been asserted "that in females who have died during pregnancy from the effects of some deleterious poison, the same specific agent which the mothers had used has been found in the blood taken from the heart of their dead infants."*

In females who are chlorotic, the blood is altered in its physical characters, and is apparently the cause of this singular disease. It is deficient in the solid or fibrinous principle, and consequently it is thin and pale, and scarcely tinged with red. The symptoms in this affection are so general, that we may safely affirm that every organ and function of the body suffers more or less.

It is not uncommon also for leeches to die immediately after they have sucked the blood of some persons. Cases of this kind have been occasionally recorded.† In these cases the presumption is, that some deleterious agent has been mixed with the blood, which has proved fatal to the leeches.

The following is a singular instance of a vegetable poison entering the circulation, and producing no injurious effect on the animal, but afterwards producing fever, and even death in those who use its milk.

A plant, which is called by the natives the *Indian Hachy*, grows in Tennessee, on the banks of the river Cumberland, and in other parts of the western district of the United States of America, and is so poisonous, that a small quantity of the milk of cows that have fed upon it, mixed with tea, produces most violent fever, and in some cases even death. The following account of the disease produced by this poison is given by Dr. Macall:—"After swallowing the milk, the person in a short time suffers from thirst, nausea, vertigo, confused or imperfect vision; vomiting often ensues, succeeded by violent fever, the exacerbations subsiding at irregular intervals. The pulse is extremely variable, sometimes strong and full, at others, tremulous, small, and corded. Constipation, which exists from the beginning, becomes more obstinate towards the third or fourth day. The skin also about

this time is more hot and parched, the eyes are red and suffused, there is very great restlessness, and all the secretions are scanty. Towards the sixth and seventh day excessive debility takes place, with very often paralysis of the tongue and other parts; and soon after ensue stupor, cold clammy sweats, convulsive hiccup, and often offensive cadaverous odour, and death."*

Dr. Haines, in his account of this disease, which the natives call *the trembles*, observes, "that the heart beats with such violence in some cases as to excite horror in the physician and bystanders. When they lay the hand upon the patient's breast, it seems to labour convulsively, and as though it were clogged in its action by a superabundance of blood. The patient feels nothing he can strictly call pain; but the sense of heat, the oppression, the palpitation of the heart, and the violent efforts to vomit, constitute an extreme degree of distress."

It is also stated that the milk and flesh of animals killed while labouring under this disease will produce disease in other animals. Sucking calves, which have had no food but the milk of an affected cow, show the peculiar symptoms, and often die of the disease. Persons also making use of the milk or butter from the same cow have become affected.

In an instance of a whole family becoming sick with this disease, (some of them in a few hours after dining upon a loin of veal,) it was afterwards satisfactorily ascertained that the calf, which was sold in the market by an unprincipled person, laboured under the disease at the time it was butchered. In another instance several persons became severely affected from incautiously eating of a pig, which had been fattened upon the milk of a cow that was known to be affected with this disease: all of the family who ate of it were seized, some of them in a few hours.

These facts lead to the conviction, that many diseases are produced by a morbid state of the blood.

We formerly adverted to the revival of the opinion among modern pathologists, that a certain class of fevers arise from this source. Many writers who have observed the fevers of hot climates, (Warren, Hume, Hillary, Stevens, and others,) describe the altered state of the blood in the ardent malignant fevers, and from the accounts given by some physicians of the fevers of hot climates, it is more than probable that the diseased state of the blood precedes and is the cause of the febrile symptoms.

In the Genesee country (the lake country of the United States) there are extensive swamps, so that in the hot months there are certain localities in which fever prevails extensively. Dr. Stevens states that during his residence in that country he bled several individuals who resided in some of the most sickly places, but who had not yet been at-

* Observations on the Healthy and Diseased Properties of the Blood, by Wm. Stevens, M.D.

† Christison on Poisons. Medical Gazette, February, 1831.

* Philadelphia Journal, 1822.

tacked with the fever. The blood was very dark in colour, and evidently deranged in its properties.

Dr. Potter, with the view of proving the non-contagious nature of yellow fever, which had been very fatal at Baltimore, observes, "it was remarkable in all cases in which it was deemed expedient to bleed, the blood wore the same general appearances. After a separation had taken place, the serum assumed a yellow shade, often a deep orange, and a portion of the red globules was invariably precipitated. It occurred to me, that if the remote cause resided in the common atmosphere, the blood of all who had inhaled it a certain time would exhibit similar phenomena. It accorded with the pathology I had conceived to conclude, that all who lived in an atmosphere so inquinated were constantly predisposed, and that an additional or exciting cause only would be required to develope the symptoms in form. To ascertain the appearances of the blood in subjects apparently in good health, I drew it from five persons who had lived during the whole season in the most infected parts of the city, and who were, to every external appearance and inward feeling, in perfect health. The appearances of the blood could not be distinguished from that of those who laboured under the most inveterate grades of the disease. As this experiment might have been considered inconclusive, unless the blood could be compared with that of those who lived in a purer atmosphere, remote from the evolution of miasmata, I selected an equal number of persons who dwelt on the hills of Baltimore county, and drew from them ten ounces of blood. The contrast in the appearances was so manifest, that no cause for hesitation remained. There was neither a preternaturally yellow serum nor a red precipitate: the appearances were such as we find in the blood of healthy subjects. A young gentleman having returned from the western part of Pennsylvania, on the 10th of September, I drew a few ounces of blood from a vein on that day; it discovered no deviation from that of other healthy persons. He remained in my family till the 26th of the month, and on that day I repeated the bloodletting. The serum had assumed a deep yellow hue, and a copious precipitate of red globules had fallen to the bottom of the receiving-vessel. Of the six persons whose blood assumed those indications of the remote cause, four were seized with fever during the epidemic; the other two escaped any formal attack, but complained occasionally of headach, nausea, and other indications of disease. Hundreds who were not confined, and who never took medicine, experienced the effects of the general cause, under a variety of forms, such as nausea, giddiness, headach, constipation, a pale or yellow face, tinnitus aurium, pains in the extremities, and some other light shades of incipient indisposition. In some there were premonitory symptoms of a formal attack; in others they vanished, leaving the subject in

his usual health. Many were listless, complaining of universal languor, indisposed to muscular exertion, yet did not surrender to the disease. They were neither sufficiently indisposed to be placed on the sick-list, nor well enough to pursue their ordinary occupations."*

With respect to the state of the blood in fevers of temperate countries, Dr. Mead says, "Pestilential fevers, in fine, I call all those which are accompanied with some sort of poison. Now of whatever nature this happens to be, it not only infects and corrupts the blood, but seizes upon the subtle nervous liquor. Hence it is, that these fevers act with greater rapidity and violence, and are much more fatal than the common sorts."

Dr. Stoker conceives typhoid or adynamic fever to be generally symptomatic of morbid changes in the physical character of the blood. He states that the crassamentum is dissolved, or broken into fragments, tinging the serum with its colour, which is sometimes of a very dark brown, and sometimes of a greenish hue. These changes he considers to be intimately connected with disturbance or failure of the vital power in the process of sanguification; and that the morbid changes which take place in the blood become, in proportion to their degree, the source of morbid action.†

Dr. Clanny has adopted views nearly similar, from observation of the gradual changes in the blood from the commencement to the decline of fever.‡ He has shewn the difference in the component principles of the blood according to the stage of the disease, that the blood loses a proportion of its solid ingredients as the fever advances, which it afterwards gradually regains as the fever declines. He firmly asserts his belief, however, in these various changes in the blood being the effect of disease in the solids.

The idea, that certain forms of fever originate in a morbid condition of the blood, is further supported by the peculiar symptoms which follow from poisonous wounds in dissection, or in the preparation of putrid game. The symptoms in these cases closely resemble those of typhous fever, and the description given of the effects of introducing putrid fluids into the veins of animals. Whether the opinion of the older writers, that in fevers originating in contagion the contagious principle alters the properties of the blood, be correct or not, we certainly think the strong analogy in the cases alluded to tends to confirm the supposition of typhoid fevers originating in diseased blood.

There has been much ingenious disputation on the question, whether the alteration in the blood be the cause or the effect of the disease in the solids. It appears probable, if not

* Memoir on Contagion, more especially as it respects the Yellow Fever, by Nathaniel Potter, M.D. Baltimore, 1818, p. 53.

† Report of the House of Recovery and Fever Hospital, Cork-street, Dublin, 1829.

‡ Lecture upon Typhous Fever.

certain, from what has been advanced, that in a certain class of fevers (typhoid) the blood is primarily diseased, and that certain changes in one or more organs take place as a consequence, or secondary effect. On the other hand, from various circumstances, as well as from some recent experiments (by Dupuytren, Mayer, and Dupuy), it may be inferred that the solids, more particularly the nervous system, effect most important and sensible changes in the constituent principles of the blood.

On this subject Andral remarks that "no line of demarcation can with strictness be drawn between the blood and the solids. Physiologically speaking, it is impossible to conceive that one of these two parts of the same whole could be modified without the other being so likewise. On the one hand, inasmuch as the blood nourishes the solids, and as, without its presence, they cannot support life, the state of the solids cannot but be influenced by the state of the blood. The chemist might as well say that the nature of a body does not depend on the nature of the elements that compose it. On the other hand, the solids, considered with respect to their relations to the blood, form but two classes; the one contributing to *make* the blood, such as those concerned in the actions of absorption, digestion, arterial circulation, and respiration; the other contributing to *unmake* it, those, namely, concerned in the actions of venous circulation, secretion, and nutrition. No one solid, therefore, can undergo the slightest modification without producing some derangement in the nature or quantity of the materials destined to form the blood, or to be separated from it. Physiology then leads us to the conclusion, that every alteration of the solids must be succeeded by a modification of the fluids. Viewed in this light, there is no longer any meaning in the disputes between the solidists and humorists; the system appears to constitute but one great whole, indivisible in the state of health as well as in that of disease. The division of the parts of the body into solids and fluids seems to be a distinction of small importance, and one that is not always just, since it ceases to exist in the intimate structure of the organs, in which all the grand vital phenomena take place, and in which also occur all the changes that constitute the morbid state."

It is probable that when certain external agents alter the properties of the blood, and thus induce fever, the changes take place in a very gradual and almost imperceptible manner. If, for example, an individual who has been accustomed to a pure air, be exposed to an unhealthy tainted atmosphere, or to marsh miasms, or if his food be of an unwholesome kind, or insufficient as to quantity, he is observed gradually to droop, to emaciate, and to lose his natural energy: he may for a long time struggle against this incipient form of disease, but at length symptoms of fever become developed. Under these circumstances, it is very probable that the blood has been undergoing

gradual changes from the time that the system was first exposed to the causes adverted to; in the one case, the unhealthy atmosphere has altered the qualities of the blood; in the other, the unwholesome kind or scanty supply of food has produced bad chyle, which, by entering the circulation, taints the general mass of the blood.

It would thus appear, that when the various exciting causes produce fever by their action on the solids, the febrile phenomena take place speedily, while those acting on the blood produce their effects in a gradual, slow, and often imperceptible manner.

Treatment of continued fever.—Before deciding on the measures to be adopted in the treatment of any disease, it is requisite that the practitioner should have correct ideas of its nature in order that the principles or indications of cure may be successfully applied.*

In no class of maladies is this more essential than in continued fever, which, we have seen, assumes so many modifications, arising chiefly from the various circumstances in which it originates, and the local inflammations with which it becomes complicated. When those points are considered, it will be evident, that the treatment must be adapted to the circumstances of each case. Not only are the precise form of the fever, and the presence or absence of local congestion or inflammation to be ascertained, but the duration of the disease, the age, the sex, and the constitution or powers of the individual—the previous habits or mode of life, the effects of remedies which may have been previously employed, and the character of the prevailing epidemic. Sydenham's remark should ever be imprinted on the practitioner's mind, that the same method which cures in the middle of the year may possibly prove destructive at the conclusion of it; and when he had fallen on the method of treating any species of fever, he was always successful till that species became extinct and a new one arose, when he was again doubtful how to proceed; and, notwithstanding his utmost caution, could scarcely ever preserve his first patients from danger, till he had thoroughly investigated the nature of the disorder.

The ancients entertaining the opinion that the phenomena of fever were the result of certain efforts of the system to expel some noxious agent, observed most carefully the various changes which took place when the symptoms were allowed to run their natural course. They, consequently, watched the spontaneous efforts of the system, and the supposed salutary effects of certain critical evacuations in controlling or removing the various morbid actions. Founding their indications on attentive observation of the va-

* Sentio autem, nostræ artis incrementum in his consistere, ut habeatur historia sive morborum omnium descriptio, quoad fieri potest, graphica et naturalis, praxis seu methodus circa eosdem stabilis ac consummata.—Sydenham.

rious means by which the system apparently effected a natural cure, they did not attempt to interfere with its operations, but were contented to assist these natural efforts by such measures as they conceived most likely to conduce to this end.

Accordingly, the older physicians attempted the cure of fever by promoting, by artificial means, such evacuations as are occasionally noticed to occur when the disease is allowed to pursue its own course, uninterrupted by the interference of art. The symptoms or evacuations which are observed in the spontaneous resolution of fever, and which physicians have attempted to induce by remedies, are vomiting, diarrhoea, sweating, and hemorrhage.

Another mode of treatment has been proposed on the principle that, as fever is frequently a fatal disease, the attention of the practitioner should be directed chiefly to combat the more dangerous symptoms which arise in its progress; and we confess that, in our judgment, this plan is not only more philosophic, but that which is most successful in practice.

We have just stated the indispensable necessity of ascertaining the form of the fever before the indications of treatment are considered; and, as the measures to be pursued are essentially different, according to the type of the disease, we shall treat of the management of each variety in the order of the description given in the history.

Treatment of simple fever.—In the management of the milder as well as the more severe cases of the common epidemic fever, the practitioner would often be more successful in his endeavours to cut short the disease, or to lessen its duration, were medical aid resorted to on the first feeling of indisposition. It too often happens that the primary stage is altogether neglected; the patient, hoping that the symptoms will pass off, and unwilling to believe that he is seriously indisposed, continues to pursue his usual avocations, until he is compelled by increasing illness to resort to medical aid.

In investigating the symptoms of fever, however apparently mild, the condition of the several organs should, in the first place, be carefully examined by every means within our reach, that we may be certain there is no lurking disease to keep up the febrile excitement. The patient, his relatives, and sometimes his medical attendant, are too apt to suppose, that if there be no pain to attract attention to any organ, there is no local disease going on. A very short acquaintance with acute disease, however, will convince the practitioner that, besides pain, (which in many cases of local inflammation is entirely wanting,) there are other symptoms, the presence of which indicates both the seat and intensity of the local affection. Again, when we find one organ more particularly affected than another, although the disturbance be merely functional, this over-action, which often depends on irritation or congestion, should be watched and

controlled, lest it should pass into inflammation.

Having ascertained the condition of the several organs, and being satisfied that there is no local complication, the modified antiphlogistic treatment is to be adopted. Strict quietude should be enjoined; consequently confinement to bed, or at all events to the horizontal posture, abstinence and cessation from all mental effort, are indispensable; fortunately, indeed, the lassitude and languor which attend the very first approach of fever, render the patient averse to exertion either of body or mind.

In every form of fever, the expediency of bloodletting is to be considered. This remedy is not to be indiscriminately employed; but the circumstances of each case weighed, before the practitioner decides on employing or withholding the lancet. We shall therefore consider the circumstances which should regulate the employment of this remedy, as we treat of the measures to be pursued in the various forms of fever.

In the milder varieties of simple fever, bloodletting is seldom required, unless the patient be of a full habit, or the symptoms indicate unusual excitement. Under these circumstances, a moderate bleeding at the commencement of the disease is often of much service in mitigating the symptoms, and preventing local inflammation. Indeed, there are few cases of the acute fever of temperate countries, in which, at the onset, a moderate bleeding is not advisable; and in the fevers of hot climates, which often run their course with alarming rapidity, this evacuation is indispensable.

Physicians of observation and experience have often remarked the different characters of epidemic fever, and are therefore aware that at one period, or in some epidemics, the type of the fever renders the bold use of the lancet necessary, while at another season, or from some peculiarity in the epidemic, which is quite inexplicable, the system will not bear with safety the bold treatment which the previous epidemic required. The character of the prevailing fever, as well as the stage and symptoms of the case, must determine the propriety of bloodletting, and the extent to which it should be carried. Even when, from the nature of the prevailing epidemic, bloodletting is indicated, it should be restricted to the early stages, unless some symptoms arise in the later periods to require it. This remedy is also to be prescribed with great circumspection when the patient is of a feeble constitution, or advanced in years, of intemperate habits, or if there be chronic visceral disease. In such cases, unless there be symptoms which require bloodletting, the modified antiphlogistic treatment is to be adopted, viz. strict rest, antimonials, and purgatives; and should local congestion or inflammation arise, they are to be arrested by the topical abstraction of blood.

The freedom with which some physicians speculate on the safety of large bleedings in

fever has led to very improper notions on this point of practice. A little experience at the bed-side, and attentive observation of the ever varying circumstances which individual cases of fever present, will soon enable an observing, and what is of more importance, a candid practitioner, to form a true estimate of this powerful remedy. Were every patient who is seized with fever to be bled indiscriminately, without regard to age, constitutional powers, previous habits, and mode of living, and more especially to the prevailing character of the epidemic, many lives would be sacrificed by a remedy, which, when judiciously employed, is an anchor of safety.

The action of full vomiting, by the shock given to the system, and by determining the blood to the surface, being frequently followed by marked relief of the general symptoms, has led to the administration of emetics in the early stage of fever. They are therefore to be employed in cases in which bloodletting is considered unnecessary, or in conjunction with this remedy. There are few circumstances which forbid their exhibition, so that, unless, as sometimes happens, the disease be ushered in by spontaneous vomiting, or epigastric tenderness, the patient be plethoric, or there be determination to some organ, more especially to the head, or marked prostration, a scruple of ipecacuanha, with one grain of tartar emetic, may be given in a draught, and its operation promoted and rendered as little distressing as possible by copious draughts of tepid fluids.

The exhibition of purgatives in fever requires as much discrimination as bloodletting. Before the excellent practical work of our much respected friend and preceptor, Dr. Hamilton, appeared, the minds of physicians were fettered by the fear of debility, one of the supposed direct causes of death in fever, and purgatives were prescribed with great diffidence, lest by their operation the spasm of the extreme vessels, and the consequent debility, might be increased. This venerable physician pointed out, in his admirable work, and illustrated by his practice, the advantages of a more liberal employment of purgative medicines in fever. The successful result of this method of treatment, and the inferences which Dr. Hamilton deduced, tended materially to withdraw the minds of physicians from the erroneous theory of Cullen, and certainly laid the foundation of the more extended views of the nature and treatment of fever which have been recently introduced.

The principles upon which this method of treatment should be employed have been misunderstood. If Dr. Hamilton's observations be studied, it will be apparent, that while he recommends the free evacuation of the bowels in the early stages of fever, he deprecates their indiscriminate administration. After detailing the circumstances which first led to his adopting the treatment of fever by purgatives, he states, "if this be a just view of the case, the plain inference is, that, while purgative medicines preserve a regular state of the body,

they do not aggravate the debilitating effects of fever. The complete and regular evacuation of the bowels, in the course of fever, is the object to be attained. Within this limit, I have had much satisfaction in prosecuting the practice; nor have I, in a single instance, had occasion to regret any injury proceeding from it; for I am not an advocate for exciting unusual secretion into the cavity of the intestines, and for procuring copious watery stools; these, while they are not necessary, might increase the debility so much dreaded."^{*} With these precautions, no class of remedies is more beneficial in relieving the primary symptoms of fever, in preventing the accession of more formidable symptoms, and thus shortening the duration of the disease. In the more advanced stages, however, purgatives are injurious by draining too much from the system through the bowels; it is sufficient that the alimentary contents be expelled; and should the secretions, which ought to be daily inspected, appear to be vitiated, mild aperients, containing small doses of mercurial preparations, should be from time to time exhibited.

We cannot deprecate too strongly the practice of administering active cathartics in fever without reference to the circumstances of the case, and more especially to the powers of the patient. Such indiscriminate use of purgatives originates in misconception of the principles on which they should be employed. These remedies should not be prescribed merely because fever exists. In some epidemics and at certain seasons, we have seen that there is a tendency to diarrhoea. It is almost unnecessary to state that under such circumstances aperients are to be withheld, or those only given which tend to correct the morbid secretions.

The doctrines of Broussais as to the pathology of fever have had a salutary influence in checking the abuse of purgatives in the treatment. There is, no doubt, a material difference in the type of the fevers of France compared with those of Britain; there is a greater tendency to gastric irritation, and to those changes in the mucous membrane of the bowels which result from inflammation. We do not, therefore, wonder at the proscription of purgatives by the French physicians, and their extravagant denunciation of the British treatment of fevers. The fact seems to be, that if British physicians were called upon to undertake the treatment of fever in France, they would be less lavish of their purgatives; and on the other hand, after the French physician had seen the character of fever in this country, and thrown aside his preconceived notions and scholastic prejudices, he would acknowledge the utility of the judicious administration of purgatives in the treatment of the fevers of Britain.

The choice of the aperients employed is of less

* Observations on the Utility and Administration of Purgative Medicines in several Diseases, by James Hamilton, M.D.

moment than their due regulation. In the beginning of fever, especially when there is considerable excitement, the more active purgatives, such as calomel combined with rhubarb, or senna with a neutral salt, may be given. Afterwards, such as ensure a full evacuation of the bowels, according to the indication to be fulfilled, are to be employed. In cases in which purging is required, we have found a powder, containing three grains of calomel, two of James's powder, and eight of rhubarb, given at bed-time, during the stage of excitement, answer every purpose; and if a more free action of the bowels be necessary, half an ounce of castor oil, or an aperient draught, may be given in the morning. When the skin becomes cool, and the tongue begins to clean, the calomel and antimonial powder may be omitted, and the regulation of the bowels managed by rhubarb, castor oil, or senna, so as to ensure one or two moderate evacuations daily, while any symptoms of fever remain.

Sometimes the stomach is so irritable that ordinary aperients are rejected, and even increase the irritation; in such cases the bowels are to be opened by injections, by which the large intestines are unloaded, and the peristaltic action of the upper part of the alimentary canal is promoted.

When the fever is fully developed, the skin becomes steadily warmer than natural, especially towards the evening. The abatement of the febrile heat being generally followed by marked relief in the symptoms, and in the patient's general sensations, various means are employed with the view of reducing it. Those means which induce perspiration have been employed with this object.

This attempt to imitate nature was strongly inculcated by Cullen. Spasm of the extreme vessels being the supposed cause of the phenomena of fever, it was imagined that every measure which tended to diminish or remove this state of the cutaneous exhalents would have the effect of subduing the disease. Upon these grounds, the employment of diaphoretics in fever was suggested, and these remedies now constitute a part of the treatment of all febrile diseases.

It should, however, be observed that, although a spontaneous or natural diaphoresis has always a salutary effect in reducing not only morbid heat, but the other febrile symptoms, and occasionally accompanies the crisis of fever, the same relief is scarcely ever observed to follow diaphoresis induced by artificial means; and if it be attempted by stimulating or healing drugs, or confining the patient to a warm room, and loading him with bed-clothes, the febrile symptoms, instead of being allayed, are increased. If, however, moisture of the skin can be promoted by saline preparations, such as the acetate of ammonia, with antimony or ipecacuanha, assisted by tepid diluents, the morbid heat of the skin is generally reduced, and the feelings of the patient and general symptoms are ameliorated.

The employment of refrigerants is another

mode of diminishing the morbid heat of the skin in fever. Various internal remedies are prescribed with this view. The mineral and vegetable acids being useful in quenching thirst and cooling the surface, either may be employed according to the feelings of the patient; the most agreeable and convenient form of the latter is, the native vegetable acids contained in fruits, such as the lemon, orange, and tamarind. These may be taken in moderation if they agree or the bowels be not purged. Sometimes the saline refrigerants, such as the citrate or the nitrate of potash, are employed in preference to the acids. Not unfrequently the patient has a desire for cold drinks; the most grateful during the first few days of the fever being cold spring water, which, if preferred, may be freely allowed, and the diluted sulphuric or nitric acid occasionally added.

Very little dependence however should be placed on diaphoretics or refrigerants; their efficacy is very doubtful, while they often seduce the practitioner from more active measures.

A more effectual mode of reducing the morbid heat is by the free external application of cold. The admission of cool air is of much importance in all acute diseases, but more especially in fever. Those who are conversant with the treatment of fever among the poor are well aware of the favourable changes in the symptoms which are often rapidly produced, after patients are removed from their filthy abode to a well ventilated chamber, or to the ward of an hospital. The whole complexion of the disease is frequently altered in a few hours. In every case of fever the temperature of the apartment should be duly regulated; the air renewed from time to time, the linen (both of the bed and of the patient) should also be frequently changed (once a day if practicable), and the bed-clothes adapted to the heat of skin and feelings of the patient.

A more direct mode of applying cold in the treatment of fever is the application of cold water. Though this practice appears to have been known to the ancients, and to have been occasionally employed in modern times, it was not generally adopted as a remedy in the treatment of fevers till Dr. William Wright, formerly of the Island of Jamaica, published an account, in the London Medical Journal for 1786, of the successful treatment of some cases of fever by the ablation of the patient with cold water. He first adopted this practice in his own case, and states that he was encouraged to try it from personal experience of the effect of cool air in mitigating his pains. He succeeded in arresting the progress of the fever after twice applying the cold affusion. The successful issue of this case induced other physicians to give the plan a fair trial. To the late Dr. Currie, of Liverpool, however, is due the merit of having first attempted to regulate this practice from accurate observation of its effects.

When the cold affusion is to be employed, it is proper to ascertain with accuracy the tem-

perature of the patient. The instrument best adapted for this purpose is the mercurial thermometer with a small bulb, and curved at the end. The bulb is to be introduced under the tongue with the lips close, or under the axilla, the heat in these two situations being found by experiments to correspond exactly with, and to give a just indication of, the heat of the surface of the body.

The mode of applying the cold affusion is to have the patient stripped naked, and three to five gallons of water, at the temperature of 40° to 60° (Fahrenheit), thrown over him. The temperature of the water, however, must depend on the season of the year. The average temperature of water may be taken from 40° to 50°—during the summer months it varies from 60° to 70°. The degree of cold, however, is of less consequence in abating the symptoms than is generally supposed.

Water alone may be used, or vinegar or common salt may be added. There may be some slight advantages in the addition of these ingredients; Dr. Currie was of opinion that salt water, besides being more grateful to the feelings of the patient, might be applied to the surface for a length of time with much less hazard. This may be true, but we apprehend the chief advantage of the application of cold in any form, is the rapid abstraction of heat, and the sudden, general, and powerful shock given to the whole system, which induces a sudden salutary re-action.

The effect of the cold affusion, when it is applied with due precaution, is to diminish the morbid heat of skin, lower the pulse, and to induce perspiration and sleep.

As a general rule, the sooner the affusion is applied after the irregular chills of the first stage is over the better, provided the heat of skin is steadily above the natural standard. According to Dr. Currie, the safest and most advantageous time is, when the exacerbation is at its height, or immediately after its declination is begun. The heat at this period rises one or two degrees in the central parts of the body, and still more on the extremities, above the average heat. Dr. Currie, therefore, generally directed its employment from six to nine in the evening, though it may be safely used at any time of the day under proper regulations.

The following precautions are recommended by Dr. Currie, when the cold affusion is contemplated.

1. This remedy should never be used when there is any considerable sense of chilliness, although even the thermometer indicate a morbid degree of heat. If the affusion of cold water on the surface of the body be employed during the cold stage of the paroxysm of fever, the respiration is nearly suspended, the pulse becomes feeble and fluttering, and of incalculable frequency, the surface and extremities are doubly cold and shrivelled, and the patient seems to struggle with the pangs of instant death. Under such circumstances, as Dr. Currie states, the repeated

affusion of a few buckets of cold water would extinguish life.

2. Neither ought the cold affusion to be employed when the heat, measured by the thermometer, is less than, or equal to, the natural heat, notwithstanding the patient feel no sense of chilliness. This is sometimes the case towards the last stages of fever, when the powers of life are weak.

3. It is also necessary to abstain from the use of this remedy when the body is under profuse sensible perspiration, and this caution is more important in proportion to the continuance of this perspiration. In the commencement of sweating, especially if it has been brought on by violent exercise, the affusion of cold water on the naked body, or even immersion in the cold-bath, may be hazarded with little risk, and sometimes may be resorted to with great benefit. After the sweating has continued some time and flowed freely, especially if the body has remained at rest, either the affusion or immersion is attended with danger, even though the heat of the body at the moment of using it be greater than natural. Sweating is always a cooling process in itself, but in bed it is often prolonged by artificial means, and the body prevented from cooling under it to the natural degree by the load of heated clothes. When the heat has been thus artificially kept up, a practitioner, judging by the information of his thermometer only, may be led into error. In this situation, however, Dr. Currie states that he has observed that the heat sinks rapidly on the exposure of the surface of the body even to the external air, and that the application of cold water, either by affusion or immersion, is accompanied by a loss of heat and a deficiency of re-action which are altogether inconsistent with safety.*

According to the experience of Dr. Currie, if employed on the first or second day with the precautions recommended, the progress of the fever is often checked; but it is seldom successful when applied so late as the third or fourth day, though when administered about the eighth or tenth day, or even later, it moderates the symptoms and shortens the duration of the fever.

When the fever is advanced, the heat of the water should not be more than 15° or 20° below the heat of the body. Indeed, when the patient is weak, or when the fever has run on to the ninth or tenth day, sponging the body with cold or tepid vinegar and water is preferable to the cold affusion.

The advantages of the cold affusion in the acute or inflammatory forms of fever have been acknowledged by almost ever writer or practitioner who has adopted the practice. Our own experience of it certainly accords with that of others as to its efficiency in reducing the febrile heat and moderating the symptoms. We freely confess, however, that there are few patients who can be induced to

* Currie's Medical Reports.

submit to a remedy so inconvenient and so repugnant to their feelings; and unless the practitioner can shew urgent reasons for its adoption, he will generally find both the patient and relatives resist the practice. We have certainly never had the opportunity of witnessing a single case out of a considerable number, to which the cold affusion was applied, in which the fever was cut short, though all the patients felt afterwards greatly relieved, and in some the duration of the fever was probably shortened. The practice is best adapted to inflammatory fever (*synocha*) and more especially to the fevers of hot climates, which are accompanied with much greater excitement than those of temperate countries. It should, however, be ascertained in every case, before such a powerful remedy is administered, that there is no visceral inflammation: were such a powerful shock given to the system under such circumstances, dangerous and even fatal consequences might ensue.

We are, for the reasons stated, disposed to recommend in preference the cold sponging or washing of the surface, either with cold water or with vinegar and water, whenever the skin is decidedly hotter than natural. This mode is easily applied, gives the patient no fatigue, and checks those irregular feelings of heat, especially in the palms of the hands and soles of the feet, which are so annoying to the patient, besides, what is of some consequence, producing no alarm. It may not, we admit, be so permanent in its effects as the cold affusion, and certainly cannot be expected to cut short or even to moderate the duration of the fever, but as a grateful means of relieving morbid heat, reducing the pulse and tranquillizing the patient, we submit that it is equally efficacious. This circumstance, with the advantages already stated, has always led us to give the cold sponging a decided preference to the cold affusion.

Dr. Currie applied the *cool* affusion in cases where, from the continuance of the fever or the debility of the patient, the cold affusion was inadmissible. The temperature of the water employed for this purpose should be from 75° to 87°. It is, however, liable to so many objections, and has so few advantages, that in the present day it is almost entirely abandoned.

The warm or tepid affusion (from 87° to 97° Fahrenheit) has been proposed in feeble habits, and when the heat is little above the natural standard; and, according to Dr. Currie, the heat is lowered as speedily by the tepid as by the cold affusion; indeed, he asserts that in some cases the heat is more speedily lowered by tepid water. The tepid affusion is applicable to every case of fever in which the cold affusion is recommended. Its effects, however, are less permanent than those of the cold affusion, besides that it is admitted, even by Dr. Currie, that it never succeeded in shortening the duration of the fever; so that, from the fatigue and inconvenience attending its application,

and its doubtful utility, it is now scarcely ever recommended.

* Washing or sponging the body with tepid vinegar and water is much employed to reduce the morbid heat of fever, and certainly, so far as the feelings of the patient are to be consulted, it is decidedly more agreeable than the application of cold. Some patients prefer cold, others tepid sponging, the former being more grateful in the summer, the latter in the winter months. The choice may, therefore, be left to the patient, either mode of aspersion being preferable to the affusion.

The effect of mercury as an alterative, improving the secretions in fever, is so beneficial, that unless there be some special circumstance in the case to forbid its administration in fever, it should never be omitted, more especially in the fevers of warm climates, or in the more acute forms of fever of temperate countries. The large quantities of calomel (ten grains every three hours) mentioned by Chisholm and other writers, as necessary in the fevers of warm climates, are never to be attempted in the treatment of the fevers of this country. Mercury is more especially useful when the tongue is much coated, the secretions of the mouth clammy and unpleasant, and the stools dark and offensive. It is frequently alone sufficient to regulate the bowels, while at the same time the tongue becomes more clean, and the clammy disagreeable state of the mouth disappears under its use. It is not necessary to push its administration so as to induce salivation, a mild action on the gums being all that is required. When this is effected, the febrile symptoms generally abate. It may be given alone or in combination with an aperient, though we prefer giving two or three grains of the pil. hydr. or the *hydragryum cum creta*, at intervals of six or eight hours; and should an aperient be required, it may be combined with the mercurial preparation, or given alone, according to circumstances. In some individuals mercury induces such irritation as to forbid its internal administration; in such cases it should be exhibited in the form of unguent: a dram of the ung. hydr. may be inserted once a day in the axilla, where absorption goes on rapidly without the inconvenience of friction.

We have often observed the singular immunity of persons under fever from the effects of mercury. This is proved from their resisting this remedy during the continuance of the fever; but as soon as the fever begins to disappear, the mercurial action often becomes perceptible; indeed, patients who could bear the free exhibition of mercury during the fever, but in whom the remedy had been discontinued, are often easily affected by an inconsiderable quantity of this mineral in the period of convalescence.

We have stated our belief that *synocha*, or inflammatory fever, is rarely observed in this country, the few cases which occur (generally in the spring) forming a comparatively small average proportion of the ordinary epidemic fever of Britain.

In the treatment of this variety, it is necessary to keep in mind, not only the more acute nature of the fever, but the greater tendency to local inflammation. It consequently requires more bold and decided antiphlogistic measures, especially bloodletting, purging, and mercury. As it generally occurs in young plethoric persons, bloodletting should always be prescribed in the onset; this not only moderates the violence of the symptoms, but diminishes the tendency to local inflammation.

We have entered at some length into the detail of the various measures which are employed in the treatment of common epidemic fever. It is to be observed, however, that the majority of cases of mild fever do not require the several measures we have pointed out. It is impossible to lay down a general rule which will apply to every case; in one instance, the mildest measures will be sufficient to check the progress of the fever; in a second, more active treatment, bloodletting, smart purging, and the free application of cold, are necessary; in a third, in addition to these measures, mercury may be required. In short, the application of remedies must be regulated and directed by the judgment of the practitioner, according to the symptoms and the character of the epidemic.

2. *Treatment of complicated fever.*—A fever, simple at its commencement, (as far as the negative evidence of symptoms warrants the conclusion,) may become suddenly complicated with local inflammation. The symptoms by which such complications in the several organs may be detected have been pointed out, and although, as a general rule, there can be no question as to the expediency of general bloodletting in complicated fever, it is not advisable to take away the same quantity as in common inflammation. There are modifying circumstances in idiopathic fever on which local inflammation has supervened, so that we find by experience the powers of the patient must be saved for the after conflict, as the fever will certainly run on for some time after the local affection has been subdued.

Dr. Wilson Philip states, "that when visceral inflammation supervenes on idiopathic fever, we must let blood more cautiously than where the former disease exists alone; and in the determinations of blood to particular parts, so apt to occur in fevers, which more frequently consist in distention of the larger vessels of the part than actual inflammation, that is, distention of the capillaries, unless the general excitement is very considerable, it is better to attempt their removal by local than general bloodletting. If there be any exception to this rule, it respects congestion in the head, because, from the nature of the circulation, congestion there is more intimately connected with a state of general excitement than in other parts of the body."

While, therefore, the lancet is to be freely employed if the symptoms demand it, the system is not to be drained of a single ounce of blood more than is absolutely necessary.

The topical abstraction of blood in cases of local inflammation is often very beneficial, and in less urgent cases, sometimes alone sufficient to subdue the local disease. Not unfrequently inflammation creeps on in an insidious manner in feeble exhausted habits; or, as often happens, the local symptoms have been entirely overlooked at the commencement; in these instances general bleeding is inadmissible, and the topical abstraction of blood is the only mode which can with safety be employed. Again, this mode will also often require to be combined with the general measures, or should local inflammation threaten to re-appear, it may be instantly checked by leeching or cupping, and at much less expense to the general powers.

The nervous system being much involved in fever, the brain, but more particularly its investing membrane, the arachnoid, is more liable to become inflamed in its progress than any other organ; the changes which take place in this delicate and important structure being, as we have seen, in many instances, the immediate cause of death. When the symptoms indicate the existence of inflammatory action within the encephalon, no time must be lost in adopting suitable measures. The degree of sensorial disturbance, the presence or absence of pain, the existence and kind of delirium, whether of the high or low character, will point out the nature of the cerebral symptoms. If there be pain in the head, flushing of the face, hot skin, thirst, rapid pulse, acute delirium, (especially towards night,) and watchfulness, we have sufficient evidence of cerebral inflammation to warrant general bleeding, (when there is much excitement from the temporal artery or jugular vein,) followed, if necessary, by the local abstraction of blood from the forehead or nape, and a cold lotion to the scalp.

Another remedy of great power in subduing inflammation of the brain is the affusion of cold water on the scalp. This has been generally termed the *cold douche*. It is as simple in its application as it is powerful in its effects. The patient is raised in bed, the head is then held over an empty vessel, and cold water from a large jug poured on the scalp, the stream being gradually raised as the patient can bear it. A considerable shock is at first produced, but the patient, if he be sensible, expresses great relief, and generally requests it may be repeated. We have frequently seen threatened renewals of cerebral inflammation promptly checked by this treatment, which should always be employed, in some cases as an auxiliary to the other measures, or it is often alone sufficient to keep down the inflammation in weak habits, or when the further abstraction of blood is of doubtful propriety.

The application of blisters to the scalp in cerebral inflammation requires consideration. The too common plan of blistering the head in such instances, before the excitement is diminished by bloodletting, is reprehensible. The application of blisters to the head in fever

should be confined to those cases in which there is danger of the inflammatory action terminating in effusion, or to that particular state of the brain in inflammation, which, though there be no effusion, is attended by coma. Hence when, notwithstanding depleting measures have been judiciously applied, the patient becomes drowsy and insensible to surrounding objects except when roused, a blister may be advantageously applied to the occiput, while an iced evaporating lotion is kept on the forehead, and the system brought under the influence of mercury conjoined with digitalis and squill, so as to promote the action of the kidneys.

There is a form of low delirium in fever which requires to be distinguished from that arising from inflammation of the brain or its membranes. It arises from some peculiar condition of the brain with which we are unacquainted, and may be distinguished from the acute form of febrile delirium, by the pallor of the face, the bloodless appearance of the conjunctiva, the softness of the pulse, the cool state of the scalp, and the absence of muscular twitches. It occurs chiefly in feeble exhausted habits, and frequently in persons who have suffered large losses of blood in the treatment. In other instances it may be traced to intestinal irritation, or some of those lesions in the bowels which so frequently accompany continued fever. This sympathetic delirium is not relieved, but invariably increased by the abstraction of blood. It is best managed by small quantities of nourishment and opiates, with a blister to the nape.

A similar state of the nervous system is often observed towards the termination of other acute and chronic diseases, and also in states of exhaustion induced by injudicious blood-letting or spontaneous hemorrhage.

No class of medicines is more efficacious in removing cerebral inflammation than purgatives; so that, unless there be some special circumstances to forbid their employment, they should form part of the treatment in such cases.

When we have succeeded in arresting the cerebral inflammation, the patient must be strictly watched for some days, as the fever, though moderated, is not extinguished, so that the capillaries are very liable to resume the same action, and thus renew the local disease.

Bronchitis is the most frequent form of pulmonary disease in fever. It is in general easily detected, unless it assume the latent form, when it can only be recognized by auscultation. In severe cases of fever, more especially when the brain is much affected, the frequent application of the stethoscope is indispensable, in order to discover not only the existence but the intensity of this complication. The milder forms of symptomatic bronchitis subside under the use of the measures employed in the general treatment. It is occasionally necessary in addition to apply a few leeches to the chest, and to allay the cough by demulcents.

In more severe cases more active treatment is necessary. General bloodletting possesses less control over this complication than might be expected. More benefit is derived from cupping or the application of leeches to the chest, with warm fomentations diligently applied at intervals of two or three hours. The local bleeding is to be followed by antimonials and a blister. If the bronchitis be not arrested by these measures, large doses of the tartrate of antimony are to be administered. To the efficacy of this remedy we can bear testimony from ample experience. One grain, or in more severe cases, two grains of tartar emetic dissolved in an ounce of any aromatic water, may be taken every two, three, or four hours, according to the exigency of the case. The remedy almost invariably produces vomiting at first, (unless there be considerable torpor from the condition of the brain,) but after three or four doses have been taken, the vomiting ceases, and *tolerance* becomes established. In general this remedy moistens the tongue, and produces softness of the skin, or even diaphoresis; it often, however, produces no sensible effect, except that the bronchitis abates and gradually disappears under its use. When the more urgent symptoms give way, the same dose may be given at more distant intervals, till the remedy be no longer required.

It is necessary, sometimes, to endeavour to allay the distressing vomiting induced by this medicine. This is frequently effected by giving the dose of the tartar emetic in a common saline effervescent draught, to which a few drops of laudanum may be occasionally added.

If it produce purging it must be conjoined with opium; and if, notwithstanding this combination, the purging continue, the antimony must be suspended. In all cases, therefore, when the bowels are irritable, this remedy must be withheld, and the pulmonary symptoms arrested by other measures. If, again, the symptoms of fever be accompanied with great prostration, or if after a fair trial it appear to lower the general powers without subduing the symptoms in the chest, it should be at once withdrawn.

When pneumonia supervenes on fever, the treatment is to be conducted on similar principles. General bloodletting is certainly more efficacious in subduing inflammation of the substance of the lung than of the bronchial membrane, though, unless the symptoms be very urgent, we prefer free local depletion, followed by the exhibition of the tartar-emetic as just recommended, or by calomel and opium with counter-irritation. The calomel and opium may be given, in the proportion of two grains of the former and half a grain of the latter, every three or four hours, till the local symptoms are relieved, when it may be given at more distant intervals, and afterwards withdrawn.

Our experience does not lead us to form a very high opinion of the efficacy of expectorants in symptomatic bronchitis or pneumonia. We have, however, observed good effects from the addition of small doses of ipecacuanha wine,

or of the antimonial wine, to the common saline diaphoretic draught. Still we do not place much confidence in this class of remedies. When the patient is unable, from increasing prostration, to expel the expectoration, carbonate of ammonia, in doses of eight or ten grains in almond emulsion, or decoction of senega, appears often to assist its expulsion.

The occurrence of acute pleuritis during fever is by no means frequent; and when it does take place, it is chiefly in the more advanced stage, or during convalescence. The treatment is very similar to that of pneumonia—local bleeding, calomel and opium, blistering, and purging. Tartar emetic seems to possess little influence over membranous inflammation, and consequently is inapplicable to pleuritis.

The more dangerous form of pleurisy is the chronic, the danger arising from its coming on in an insidious manner, without pain, much acceleration of the breathing, or cough. It is not easily recognised even by auscultation till liquid effusion to a considerable extent has taken place, when the dull sound on percussion of the diseased side, the absence of the respiratory murmur, and the peculiar sound of the voice, (ægophonia,) point it out. The effect of curative measures depends on the state of the membrane, and the extent of the effusion. When the fluid is so considerable as to render its absorption improbable, the operation of empyema is the only resource.

It is proper, however, to bear in mind, that in a considerable proportion of cases of fever, in which pulmonary symptoms predominate, the chest affection is the primary disease, of which the fever is only symptomatic. Many of those cases commence by slow insidious pulmonary inflammation, which, from the comparatively little disturbance it causes, is often allowed to run on until a more acute attack brings the disease under the care of the physician, who has thus to contend with neglected inflammation, over which the most energetic measures too often exert an inefficient control.

When fever is accompanied with symptoms denoting disturbance of the gastric organs, a moderate bleeding from the arm, if the pulse be full, or in less urgent cases, the application of leeches to the pit of the stomach, is often sufficient to allay the irritation. Notwithstanding the relief afforded by bloodletting, it does not appear that the vomiting and epigastric tenderness depend on inflammation, as Dr. Cheyne states that in a case in which considerable tenderness of the epigastrium existed during a great part of the disease, on opening the body not the slightest morbid appearance could be discovered, except a small quantity of bloody serum effused into the cavity of the abdomen, and a very inconsiderable blush in the mucous membrane of the stomach at the cardiac orifice.

When gastric irritation continues during the course of the fever, the plan of treatment recommended in Dr. Cheyne's account of epidemic gastric fever is to be pursued.

We have seen that follicular disease of the intestines, whether primary or secondary, may be going on without being attended by any symptom of gastric disturbance. When, in addition to the ordinary symptoms of fever, the bowels are irritable, and the tongue is morbidly clean and red, or coated at the root, we may infer the existence of gastro-enteritis, or this follicular disease. Our object must then be to prevent, if possible, the destructive changes which take place, whether the intestinal affection be primary, or have supervened in the progress of the fever.

The local abstraction of blood from the surface of the abdomen (particularly from the right iliac region) is to be pursued, to an extent proportionate to the powers of the patient, and the probable duration of the affection. From twelve to eighteen leeches are to be applied, and the abdomen afterwards enveloped in a warm poultice, renewed every two hours. The leeching may be repeated every day, every second day, or at more distant intervals, according to circumstances. The more early the effective measures are resorted to, the greater the chance of preventing the stage of ulceration, which we are convinced cannot be recognized by symptoms. We are aware that Dr. Bright considers the ochry diarrhoea to be diagnostic of intestinal ulceration. We admit that in some cases in which we have found ulceration after death, the stools had this character; but in other instances the greatest variety both as to colour and consistence has been observed; in a few the stools were solid up to the time of death, and in examining the intestines there was a considerable quantity of solid excrementitious matter.

In the majority of instances, however, the stools are watery, and generally contain a large admixture of mucus. If in this condition of the bowels laxatives are improper, restraining the diarrhoea by astringents is equally injurious, unless the patient become so much exhausted by the frequency of the stools that it becomes a matter of necessity to restrain the purging; but the circumstances in which the employment of astringents becomes requisite, rarely occur.

It is a matter of great doubt to our mind how far this follicular disease, except in its primary stage, can be arrested by any plan of treatment. We are not prepared to deny the possibility of the cicatrization of intestinal ulceration, though we think that when it is extensive, the process of reparation rarely if ever takes place. The indication consequently is, to arrest the primary stage of this disease by local bleeding, and afterwards by a combination of mild mercurials with opium. The mercury is not to be pushed so as to affect the mouth; the evidence of the mercurial action on the gums being all that is necessary. Four grains of the hydrargyrum cum creta may be combined with half a grain of ipecacuanha, or, when the bowels are very irritable, with three grains of the compound ipecacuan powder. Either of these formulæ may be taken every four hours. We have sometimes found, in addition to these

remedies, the chalk mixture with laudanum, or an injection containing a drachm of laudanum, at bed-time, attended with good effects.

Dr. J. L. Bardsley of Manchester informs us, that he has been more successful in this follicular affection with a combination of superacetate of lead and opium than by any other remedy. He recommends three grains of the former with half a grain of the latter every four hours. In some cases he has doubled those proportions with marked advantage. Leeches are to be previously applied to the lower part of the belly, and afterwards blisters, or the tartar emetic plaster, and the strength supported by wine and other stimulants. This gentleman adds, that in one or two cases in which the patient had recovered from ulceration, but had perished suddenly from some accidental acute disease, on examination after death, not only was the site of the ulcerations most distinct, and their form and size defined, but unequivocal cicatrization had taken place.

Dr. Bright considers the employment of tonic remedies a point requiring nice discrimination. "With regard to the administration of tonic remedies, there is not a doubt that they are of essential importance; and that even while evidence exists of much local mischief in the bowels, it will sometimes be necessary both to support and to stimulate the system: looking indeed to the character of the ulcerations, the deep sloughs which they often form, and the dark red inflammation which surrounds them, there would be reason to suppose that such remedies might be useful: and occasionally the decidedly remittent form which the fever has assumed, has completely removed every scruple, and led to the free exhibition of the sulphate of quinine with admirable effect. At the same time there is more danger to be feared from the early use of stimulants, as long as the system is still able without their aid to support the feeble prostration, than there is risk in abstaining from stimulants a little beyond the period when they might possibly begin to act well. In a general way the system seems capable of supporting itself for a few days under that great degree of prostration which is connected with advanced ulceration of the bowels; and although we cannot determine the exact state of the ulcers in these cases, yet we find that the action of stimulant and tonic remedies is more certainly beneficial after that state of prostration has existed for some time, than when such remedies are administered with a view of obviating or anticipating the first symptoms of collapse: for when administered too soon, they frequently kindle the inflammatory action with redoubled violence, and then it is that the most appalling combination of debility and nervous excitement is seen for one or two days to precede death."*

While we are watching and endeavouring to subdue the intestinal disease, we are not to disregard the complications which arise in the other organs. The brain and nervous system

are most likely to suffer from sympathetic disturbance, which is to be moderated by leeching, cold lotions, and blistering the occiput or nape.

The diet of the patient forms a most important part of the treatment in this intestinal affection. The blandest nourishment, consisting of milk and water, or thin arrow-root, is sufficient for the early stage. When the patient becomes exhausted, chicken broth or beef-tea may be added in small quantity to the arrow-root; and should stimulants be required, a little wine may be given according to circumstances.

Treatment of typhous fever.—Most physicians who have written on continued fever, though aware of the marked difference between the synchoid and typhoid fevers, have not sufficiently insisted on the modification of treatment which the latter require. It has been too often imagined, that because the symptoms and the morbid appearances observed in the organs after death are scarcely dissimilar, and that other forms of fever do occasionally pass into typhus, the two diseases are identical. Experience, however, informs us that not only the symptoms and progress, but the effects of remedies, are essentially different.

In the milder cases of typhous fever, blood-letting is seldom necessary, and may in general be dispensed with, unless some special circumstance arise to render it expedient; such as severe pain or sense of weight in the head, flushing, intolerance of light, hot skin, and other symptoms denoting a more intense form of fever. With such symptoms at the commencement, the abstraction of a moderate quantity of blood, especially if the patient be young and of a full habit, will be proper. If, however, the pulse, though rapid, be soft and compressible, the tongue begin early to assume a brown tint, and there be considerable prostration, the loss of blood from the system cannot be sustained.

Should a low form of inflammation in the brain, chest, or abdomen, arise, local bleeding, and afterwards counter-irritation, will be the most judicious mode of treatment. The practitioner must, however, be aware, that symptoms in the progress of the disease may render the expediency of general bloodletting a nice question: for instance, inflammation in some important organ may come on suddenly and place the patient in urgent danger. The inflammation may be so acute that local bleeding may fail to arrest it; on the other hand, the complexion of the other symptoms and the duration of the fever may seemingly forbid more active measures. If the local disease be allowed to go on, the fate of the individual is inevitable; if, on the other hand, blood be drawn from the system, when either the powers of the patient, or the experience of the prevailing nature of the epidemic do not warrant the practice, the treatment which the local disease requires may destroy life. The consideration of such a case is most embarrassing, and the result, even under the most skilful management, always doubtful. The rapidity with which the blood flows

* Reports of Medical Cases.

from the vein, and its appearance when drawn, will often afford assistance. If, instead of pouring in a continued stream, it comes in drops, notwithstanding the vein has been well opened; moreover, when it coagulates slowly, the crassamentum is thin and soft, and the proportion of serum abundant, it shows that the abstraction of blood is a measure of questionable expediency. In short, though bloodletting has been recommended in typhous fever from the early ages of medicine, we find even its warmest advocates acknowledge that it is occasionally productive of harm. Sydenham states, "*Quoties mihi cum ægris res est, quòrum sanguis vel per se imbecilior existit (ut fere in pueris) vel justa spirituum copia destituitur, ut in decliviori ætate, atque etiam in juvenibus, diuturno aliquo morbo confectis, a venesectione manum tempero.*" Huxham also remarked, "that in cases in which the blood was dark coloured and exceedingly soft, the pulse often sinks surprisingly after a second bleeding, even indeed after the first, and in individuals whose pulse indicated the propriety of a second bleeding."

Sir John Pringle affirmed that many recovered from jail-fever without bloodletting, but very few who had lost much blood; and Dr. Monro confesses that he was often obliged to give cordials to support the strength after bloodletting.

The other measures which have been recommended in mild fever may be adopted in typhus. The shock of an emetic is useful at the beginning, the more so if there be nausea. When the heat of skin is above the natural standard, cold or tepid sponging is grateful, and allays the morbid heat. Frequent ventilation of the room and changes of linen are also very beneficial.

If the skin be dry, diaphoretics are useful; and should at any time spontaneous diaphoresis come on, it is to be promoted. When copious sweatings appear in the advanced stage of the disease, they should not be interfered with, unless they produce exhaustion, when quinine with diluted sulphuric acid, mild nourishment, and cordials, are to be freely given.

The necessity for purgatives will depend on the condition of the bowels. A mild aperient at the beginning is always proper, to remove any accidental accumulation. The mildest kinds, either castor-oil, rhubarb, or senna, may be prescribed for this purpose, and repeated according to circumstances. When the fever is acute, and the powers are vigorous, the expediency of thoroughly evacuating the bowels, and of abstracting from the mass of circulating fluids through the intestinal exhalents, has been already adverted to. On the other hand, indiscriminate purging is most injurious in any form of fever, but more especially in the typhoid. "I have known," Huxham remarks, "a common purge, injudiciously given at the beginning of this fever, immediately followed by surprising languor, syncope, and a large train of other ill symptoms." Besides, from the greater tenden-

cy to inflammation of the mucous membrane and follicles of the intestines in typhus, every source of irritation, and consequently the stimulus of cathartics, should, as much as possible, be avoided.

If these precautions, as to bleeding and purging, are necessary in the early stage, they are more especially so in the advanced; at which period, such aperients as remove unhealthy secretions, without producing watery stools, are to be employed, viz.—rhubarb, magnesia, or castor-oil, with occasional doses of mercurials. It is necessary to examine daily the evacuations from the bowels in typhous fever, that the appearance of the stools may be ascertained. Bloody diarrhoea is always a most alarming symptom in fever, showing a malignant form of the disease. It depends on a loaded state of the capillaries of the mucous membrane; these vessels, partaking of the general debility, are unable to resist the congestion or afflux of blood, and consequently give way to its distending force. The congestion of the mucous membrane, and consequent hemorrhage, may take place without ulceration; but when there is ulceration the blood does not proceed from the open surface, but in the way pointed out, viz.—by capillary exudation. This symptom is best managed by suspending all irritating medicines, and administering occasional doses of superacetate of lead and opium.

When the abdomen is tympanitic, purgatives only increase the distension. Injections of carminatives give most relief, though it is only temporary. We have found an injection, consisting of equal parts of the *mistura assa-fœtida* and gruel very beneficial. As the disease proceeds, it will be necessary to allow, according to circumstances, moderate support—weak animal broths, and perhaps a little wine.

We must admit that in the treatment of fever, wine is too often administered without due consideration of the character of the disease, its stage, and the condition of the several organs. Dr. Wilson Philip observes, "that the difference of opinion which prevails on this subject, has, in a great degree, arisen from physicians having attempted to apply their rules, either for or against it, to all cases indiscriminately. Whereas it would appear that the use of wine in typhus must be almost as much regulated by circumstances as that of bloodletting in synocha. Two general observations, however, appear to me to be warranted, that more or less wine is beneficial in all severe cases of typhus; and that there are few in which large quantities are not injurious." When we see a patient labouring under symptoms of extreme debility, and find them almost uniformly relieved by a large quantity of wine, it is difficult at first view to persuade ourselves that it can be pernicious. But an attentive observer will look beyond its immediate effects, and will often see sufficient reason to doubt the safety of carrying the practice very far. He will find that the temporary excitement

he thus procures, is frequently succeeded by a greater degree of debility than that which the stimulus had removed; and if he perseveres in the practice under such circumstances, the pulse, upon the whole, will gradually become more frequent and feeble, till it ceases altogether."

Wine is seldom necessary in the early stages of fever, nor, as a general rule, at any period of the acute forms, unless, as occasionally happens, unexpected exhaustion come on, or towards the decline of the disease the powers give way. Under these circumstances, a few ounces of wine, if the skin be cool, the pulse soft, and the tongue moist, will frequently improve the condition of the patient.

In determining the propriety of administering wine in fever, the decision may in some measure be regulated by the character of the disease. We have repeatedly alluded to the difference in the type of epidemic fever. This, in our own experience, has been remarkably illustrated in the epidemic constitution of the last three years. In 1829, fever required most decided antiphlogistic treatment, as the records of the London Fever Hospital will prove. In 1830 and 1831, the symptoms assuming a low typhoid form, (which has continued up to the present time,) a more cordial or stimulant treatment became necessary. This shows that the general character of epidemic fever may at times be such as to require a stimulant plan of treatment.

Besides the indications for the administration of wine deduced from the nature of particular epidemics, there are some special symptoms which render its exhibition necessary.

1. It is sometimes observed, that when a patient in fever has been going on favourably, the pulse becomes suddenly soft and compressible, the skin cool and damp, accompanied with feeling of considerable exhaustion, and desire for wine. With these symptoms, there need be little hesitation in allowing six or eight ounces of wine in the twenty-four hours, at proper intervals.

2. When the symptoms denoting sensorial disturbance,—languor, low muttering delirium, coma, muscular tremor or subsultus, progressively increase; if, at the same time, the patient lose his strength from day to day, the pulse be soft, and the skin cool, wine may be safely prescribed.

3. When the fever assumes the petechial character, more especially if the spots be large and of a dark red or livid colour, wine is indicated.

4. In cases of sudden or unexpected collapse, which sometimes comes on without ostensible cause, though more frequently after bloodletting, protracted diarrhoea, or spontaneous hemorrhage, wine is a most effectual remedy in raising the exhausted powers of the patient.

5. Wine may be necessary to promote the convalescence in particular cases.

Another circumstance with regard to the employment of wine in fever requires to be noticed. Local inflammations not unfrequently arise in

feeble habits, or in the advanced stage of low fever, requiring general or local bloodletting. The treatment necessary to subdue the local disease lowers the general strength: the patient does not rally, but remains stationary, and perhaps loses ground and feels exhausted. In such cases, a moderate quantity of wine, provided the pulse be soft and the skin cool, is followed by excellent effects. We have often been obliged to prescribe the local and even general abstraction of blood for some sudden emergency, and in a few hours afterwards found it necessary to have recourse to the administration of wine. In such cases it should be withdrawn as soon as the powers have been restored.

Dr. Graves is of opinion that when general symptoms indicate the propriety of administering wine and opium in fever, these remedies should be prescribed, although particular symptoms apparently render the propriety of their exhibition doubtful. Dr. Graves thinks advantage may often be derived from wine and opium at an advanced period of fever, when the tongue is coated with dry brown fur, and the teeth and gums covered with sordes—when there is suffusion of the eyes—dry hot skin, heat of the scalp and flushing—a low form of delirium, with muscular tremor and subsultus—sense of weight or pain in the head, not of the acute throbbing character—and rapid, soft, or small thrilling pulse.

When the symptoms alluded to by Dr. Graves are manifest at the advanced stage of fever, we apprehend they arise from some latent local disease which has not been overcome, or has been partially renewed, and requires the adoption of local remedies suited to its intensity and the powers of the patient. We have admitted that a general stimulus, such as wine, is by no means incompatible with the local measures which are necessary to subdue low typhoid inflammation; and in offering these precautions we feel we are corroborating the opinion expressed by Dr. Graves on this subject. His remarks, indeed, are accompanied with such precautions, as shew he is aware of the necessity of guarding the inexperienced practitioner against the indiscriminate exhibition of wine and opium in fever.*

With respect to the quantity and mode of administering wine in fever, it may be remarked that it is impossible to give any general rule on this subject. The quantity must be regulated by its effects. Some of the older authors prescribed wine apparently without regard to quantity; we find on record cases of typhous fever, in which two and three bottles of madeira or port have been allowed in twenty-four hours. It would appear from these histories, that in certain forms of low fever, the system is nearly insensible to the effects of stimulants. Incredible quantities of wine have been taken by persons unaccustomed to wine without any signs of intoxication, or any other

* Dublin Journal of Medical and Chemical Science, No. 3.

perceptible effect except that of increasing the volume of the pulse, abating the delirium and muscular tremor, and restoring the heat of skin.

In the present day physicians seem less disposed to sanction extravagant doses of wine. Dr. Bateman was not inclined to exceed a pint in twenty-four hours; and enjoined, that after the object with which it is administered has been obtained, this quantity should be diminished or withdrawn, when the first symptoms of over-excitement appeared. The quantity should not be less than four, nor exceed sixteen ounces, in the twenty-four hours, unless under circumstances of sudden and extreme exhaustion, when a larger quantity may become necessary. It should always be given in small quantities, (from half-an-ounce to an ounce,) mixed with water, or some light farinaceous food, arrow-root, sago, or thin panado, the period between each dose varying according to the allowance. It is better to commence with a small quantity, and as the fever advances, or the debility increases, to augment it cautiously, and to watch its effects.

It is necessary also to bear in mind, that the quantity of wine should be regulated by the age and constitution of the individual. Young persons are not only more easily excited than those advanced in years, but in the latter the symptoms requiring the use of wine more frequently occur, and increase more rapidly.

The previous habits of the individual must also be considered; if he have been accustomed to live generously, and consequently to the use of wine and other stimulants, the allowance of wine must be greater, than in a person whose mode of living is more simple.

If we find that the pulse is quickly raised, the heat of skin increased, and the face becomes flushed, and the patient restless or incoherent, we may consider the quantity is either too large, or that the use of wine is improper. Again, if its effects soon pass off; if the patient, a short time after being stimulated, lapse into his former state of exhaustion, or seem to get weaker after each portion of wine, its longer continuance will be of little avail. On the other hand when there is a gradual and steady improvement in the symptoms, without any marked excitement after the wine has been taken; moreover if the patient relish the wine, and especially if it tranquilize him, we may confidently anticipate that it will be beneficial.

When the purposes for which wine has been given have been accomplished, it should be gradually, not suddenly, withdrawn, and the patient watched; as we have not unfrequently witnessed the train of symptoms, for which wine was first administered, renewed shortly after it has been discontinued.

The particular kind of wine is a matter of less consequence than the quality of that selected. We generally prefer the dry wines; sherry or sound Madeira, which are less likely to disagree than the red wines.

Brandy, largely diluted, is sometimes given

in preference to wine. Brandy being about double the strength of wine, when it is prescribed as a substitute, one-half the quantity stated may be ordered.

Fermented liquors are sometimes given in fever, and when a more mild stimulus than wine or brandy is wished, they are well adapted to the purpose, particularly when bottled.

Yeast has been employed in fever accompanied with putrescent symptoms, when the existence of inflammatory complications seems to contra-indicate stronger stimuli.

In some cases of extreme prostration, yeast has been given in combination with wine and other cordials. Dr. Stoker, who seems to have used it more extensively than any other physician of the present day, speaks highly of its efficacy, after a trial of its powers for upwards of thirty years, both in public and private practice. He has administered it in cases where purple extremities or gangrenous sloughing took place, accompanied with symptoms of inflammation. The result of his experience is, that barm or yeast is well suited to every stage of typhous fever in which it can be borne by the stomach. It is in general easily taken alone, or with any medicine that it may be deemed advisable to join with it; but, in the worst forms of typhous fever, when it is most needed, it not only is seldom rejected by the stomach, when any other medicine can be retained, but the patient, in such cases, often expresses a liking for it. According to this author, yeast, being moderately laxative, often supersedes the necessity of repeated doses of purgatives; but, if required, an aperient tincture may be added to it. Should, however, the bowels be purged, a few drops of tincture of opium should be added to each dose. He ascribes its efficacy to its power of correcting the morbid contents of the alimentary canal, and consequently the symptoms of putrescence, and asserts that, in his idea, petechiæ and black loaded tongue will be found more effectually remedied by it than by any other medicine. In adverting to the objection to this remedy, that it may be likely, by promoting fermentation, to increase the tendency to tympanitic distension, Dr. Stoker states, that in some of the most obstinate cases of tympanitis, enemata of yeast and assafœtida have proved the most efficacious remedies.

When yeast is administered internally, two table spoonfuls may be given in water, or with an equal quantity of camphor mixture, every three hours. If the stomach be irritable, four ounces mixed with an equal quantity of barley gruel may be administered by injection. From our personal experience of yeast, we certainly think it a remedy deserving attention in the low forms of fever.

Various other stimulants have been occasionally prescribed, alone or in conjunction with wine, in typhus. The carbonate of ammonia, combined with nitrous ether and aromatic confection, has been thought useful. We have certainly observed, that in cases in which a sudden and diffusible stimulus, less perma-

nent in its operation than wine or brandy, has been indicated, this combination has answered the purpose. We have seen it useful also as an expectorant in the symptomatic bronchitis of fever.

Another class of stimulants of a less diffusible character has been employed in the treatment of fever, viz. tonics. Of these, the vegetable tonics have been chiefly employed, more especially the cinchona or Peruvian bark, which, after sustaining more varied reputation than any other remedy in the *Materia Medica*, was at length admitted to possess superior febrifuge powers to any drug which has been discovered. When first introduced, it was prescribed chiefly in periodic fevers, but soon after acquired equal reputation in the treatment of continued fever. Its indiscriminate administration, however, without regard to symptoms or the period of the disease, has tended to diminish the confidence formerly reposed in its virtues. In the present day it is scarcely employed in the acute forms of fever, unless some particular symptoms arise, or when the fever towards its decline assumes the typhoid character.

Dr. Cullen remarks, that wherever blood-letting is proper in continued fever, bark is always prejudicial. The opinion of Dr. Bateman on this point is exceedingly strong. He states that, in the early part of his practice, agreeably to the doctrine of the times, he resorted to the decoction of cinchona on the first appearance of languor and debility. The increase of the symptoms was easily imputed to the intractable nature of the disease, or deemed the necessary result of its progress, until it became obvious, from the repeated occurrence of the fact, that the tongue, which had been, on the day before the administration of the bark, moist, and exhibiting a moist or yellowish mucous fur, was on the following morning dry or even brown; that the skin was hotter or more parched, with a flush in the cheek; that the pulse was quicker and harder; the thirst increased, and the sleep more disturbed. Dr. Bateman was so convinced that these symptoms were to be ascribed to the use of bark, notwithstanding the patient had made some progress towards recovery, that he scarcely ever prescribed it even during the stage of convalescence.

Our own experience is, that in the early stage of common epidemic fever, any preparation of bark is decidedly injurious. When the symptoms of fever have completely subsided, no tonic or stimulating remedy is needed, unless the patient be much enfeebled, and the strength slowly recovered. In such cases tonics are sometimes useful, and certainly none of the vegetable class is more powerful than bark in the form of the quinine. But we hold its exhibition in the early stages of fever under any circumstances improper, as tending, by its stimulant powers, to keep up or increase the febrile action in the system; and when there is local complication, it is

evidently so pernicious that scarcely any practitioner can be so ignorant of the common principles on which the treatment of fever should be conducted, as to think for one moment of its administration under such circumstances.

When the fever is of the typhoid form, and the symptoms, as the disease advances, denote failure of the powers, more particularly if the pulse become soft and compressible, the skin covered with petechiæ, and there be tendency to gangrene, bark, in addition to nourishment, wine, and other stimulants, may be given with the best effects. The sulphate of quinine combined with sulphuric acid is the best mode of administration.

Infusions of some of the other vegetable tonics, serpentaria, cascarilla, calumba, &c. have been proposed as substitutes for the cinchona. As stimulants they are less powerful, and when a light vegetable tonic is desirable, the infusion of any of these may be advantageously prescribed, with or without the addition of an aperient, according to the state of the bowels.

Opium and other narcotic substances have been administered in fever with two indications: 1st, as stimulants when the powers are sinking; 2d, to tranquilize the nervous system, and to procure sleep. The use of opium, as a general stimulant in fever, has been abandoned, wine being proved more safe and durable in its effects.

From the stimulant effects of opium it is injurious in the acute forms of fever, more especially when local inflammation exists. In the early stages it is inadmissible, and indeed much discrimination is required to detect the symptoms which indicate its administration. The delirium and wakefulness of subacute inflammation of the brain is best overcome by topical bleeding, and the application of cold lotions to the scalp; and when the morbid condition of the brain on which the want of sleep depends is removed, the patient generally enjoys intervals of refreshing sleep. In other cases, a state of distressing restlessness with obstinate wakefulness remains, exhausting the patient, and adding greatly to the sufferings. If, with these symptoms, the pulse though soft be rapid, the skin cool, the face pale, the tongue moist, and there be no suffusion of the eyes, opium often acts like a charm. If, however, its exhibition be followed by increase of delirium, thirst, and heat of skin, or if the tongue become dry, and the bowels confined, it should be discontinued.

We do not however think, that in every case the opium should be withheld, if the tongue be dry and even furred, as we have often seen this remedy decidedly beneficial when the tongue was in this state, if the other symptoms indicated its exhibition.

Dr. Stokes has proposed the administration of large doses of opium in peritonitis from intestinal perforation. In these cases the usual antiphlogistic treatment is inadmissible, from

the sinking of the vital powers, which rapidly supervenes. When effusion of the alimentary contents through the perforation takes place, the fatal issue is inevitable. In some few instances, nature, as we have already observed, makes an attempt to repair this lesion; adhesion of the bowel, at the point of perforation, to some portion of the intestine, or adjacent viscus, is sometimes formed, and thus effusion into the abdomen is prevented. When this occurs, the peritonitis is limited in extent; and to these cases the administration of opium is well adapted. Dr. Stokes states, that in the treatment, the first indication is to support the strength of the patient, as far as this can be done without injury; the second, to prevent the further effusion in the peritoneal cavity, by endeavouring to induce organization and adhesions of the effused lymph. This latter indication is best fulfilled by time, and by attempting to diminish as far as possible the peristaltic motion of the intestines. For this purpose opium is to be given in repeated doses. Solid opium, in grain doses, or the black drop in doses of five drops, is recommended to be given every second hour till the symptoms of abdominal inflammation abate, after which the dose is to be given at more distant intervals. In one case, though unsuccessful, this treatment afforded decided relief. Sixty drops of the black drop were given in the twenty-four hours. In another, in which recovery took place, one hundred and five grains of solid opium (exclusive of anodyne injections) were administered without the patient experiencing any of the usual effects of this remedy when exhibited in large doses.*

We think this suggestion of Dr. Stokes valuable, even in those cases in which the fatal issue is inevitable, in consequence of rapid and extensive peritonitis from effusion of the contents of the bowels into the abdominal cavity; it is the best palliative mode of treatment; and in partial peritonitis, when nature attempts the reparative process, it gives the patient the best chance of recovery.

The form in which opium is prescribed is a matter of less moment than a correct knowledge of the circumstances which indicate or forbid its employment. We have found a full dose of solid opium, (one or two grains,) answer every purpose. But we certainly prefer the acetate or the muriate of morphia, in doses of half a grain dissolved in distilled water. Some physicians prefer minute doses of opium at certain intervals, so as to keep the nervous system under its influence. We have tried this mode, but deem it less efficacious than a full dose administered at once.

The other narcotics—hyoscyamus—camphor—cicuta, are very inferior in efficacy to opium. They may, however, sometimes be advantageously combined. The extract of poppy, in doses of eight or ten grains, is often a pleasant

opiate. We have also found fifteen or twenty grains of camphor, combined with a quarter of a grain of acetate of morphia, an excellent formula.

The practice of applying blisters in fever was adopted by the older authors to produce a stimulating effect in the advanced or sinking stage of the disease. There can be little question of the effect of rubefacients and vesicants in exciting the system in phlogistic states, but we apprehend their efficacy in rousing the vital powers when the nervous system is oppressed is very questionable, and that, consequently, their value as general stimulants is doubtful.

Blisters and rubefacients are, however, applications of great utility in the local inflammations which occur in fever. They may be employed with this view as auxiliaries to other antiphlogistic measures; or in cases when the vital powers are so low that even local blood-letting cannot be adopted, they may be applied at once, as near the inflamed organ as possible, with the best effects.

Blisters are not, however, to be prescribed without discrimination, as injurious consequences often arise from their injudicious application.

In the acute forms of fever with local inflammation, they should never be employed till more active measures have been adopted. When the capillary congestion has been reduced by local or, if necessary, general blood-letting, should pain or any other symptom indicate that the local affection has not been wholly subdued, the application of a blister to the neighbourhood of the inflamed organ will often remove the disease. If it be applied without this precaution, it will invariably increase the very action it was intended to subdue. Even with the circumspection recommended, we have repeatedly seen the local disease renewed by the stimulus of a blister. It is, therefore, by no means always safe to adopt counter-irritation in the more acute forms of fever, notwithstanding the too common practice of at once applying blisters on the first appearance of local inflammation, without the precaution of previous depletion.

In the inflammations which arise in typhoid fevers, blisters are excellent local remedies, and we certainly think they are more useful in this than in any other form of the disease. In the low kind of cerebral inflammation, with tendency to coma, after leeching, the application of a blister to the occiput, with a cold lotion to the anterior portion of the scalp, is followed by the best effects. Some physicians think that in these cases a sinapism or a blister to the lower extremities is of great service, and explain the efficacy of these applications on the principle of revulsion. We have certainly seen excellent effects result from them.

Cases are recorded in which boiling water has been applied to the extremities with the object of producing sudden and powerful revulsion in severe cerebral affection in

* Dublin Journal of Medical and Chemical Science, May 1832.

fever. In extreme cases this may be adopted, but from the severity of the measure it can never be generally pursued.

In the secondary pulmonary affections which frequently arise during fever, local bleeding by leeches or cupping, and afterwards blistering the chest, is the best mode of treatment. When the symptoms have been overlooked on their first appearance, or when the strength will not admit of any form of bloodletting, counter-irritation is the only local treatment that can be employed.

In the chronic stage of the intestinal disease to which we have so often adverted, blistering the abdomen is decidedly beneficial. This practice is however by no means applicable to the acute stage of gastro-enteritis; indeed the application of a stimulus so powerful must inevitably increase the inflammatory action.

It is necessary to bear in mind, that in the typhoid forms of fever blisters do not always heal kindly. The blistered surface, assuming an unhealthy aspect, gradually degenerates into a troublesome species of ulceration, which keeps up feverish irritation in the system. When blisters either do not rise at all, or become troublesome ulcers, it is always an indication of a dangerous fever. We have certainly seen the fatal issue hastened by the effects of a blister.

With regard to the milder forms of counter-irritation, we have seen, in slight cases of local disease, sinapisms very useful. The epigastric tenderness with irritation of the stomach which occasionally appears in the early stage of fever, is often at once removed by the application of a mustard poultice to the epigastrium.

In the gastro-enteritis of fever, cloths soaked in oil of turpentine, and kept constantly on the abdomen, have been applied in order to produce counter-irritation and revulsion. When circumstances prevent the use of blisters, this application may be substituted, though it is much less powerful than either mustard or cantharides.

In all cases of fever, more especially with cerebral affection, it is exceedingly important to examine the state of the bladder. When there is retention of urine, the catheter should be employed. The practitioner requires also to be vigilant when the urine is passed involuntarily; in these instances, from the paralysed state of the muscles concerned in the expulsion of urine, the bladder becomes distended, its muscular coat ceases to contract on its contents, and from a small quantity being occasionally voided involuntarily, the medical attendant is apt to be satisfied with the report of the nurse, that there is no accumulation in the bladder. The tympanic enlargement of the abdomen may prevent the distended bladder being felt, so that in these cases the catheter should be occasionally introduced to ascertain the state of this organ.

We have already alluded to the revival of

the theory, that a vitiated state of the blood is the cause of some forms of fever.

A mode of treatment founded on this view has been proposed by Dr. Stevens, on the supposition, that in fever, but more particularly in the malignant forms, the vitality of the blood is lessened, and the quantity of its saline ingredients, especially the muriate of soda, ultimately diminished. He considers that the natural saline impregnation of the blood is the cause of its red colour, and that the diminution of its salts is the reason of its black and vapid condition in the last stage of fever.

On this theory Dr. Stevens recommends, after reducing excitement at the commencement by bleeding, purgatives, and other antiphlogistic measures to prevent serious injury to any of the organs, the administration of a sufficient quantity of non-purgative salts, with the object of restoring to the blood the proportion of saline ingredients it has lost. After this has been done, in place of lessening the quantity, it is necessary to remedy the diseased quality of the blood, by correcting acidity, if it be present, by alkaline carbonates, and afterwards throwing into the circulation an extra supply of those stronger salts which act directly on the blood, reddening its colour, correcting its diseased properties, and adding to its power of stimulating the heart.

For a considerable time after Dr. Stevens commenced the saline treatment, he used (except when there were symptoms of acidity in the stomach) a strong solution of the muriate of soda with nitrate of potash; but he has subsequently preferred another combination, consisting of twenty grains of the muriate of soda, thirty grains of the carbonate of soda, and eight grains of the chlorate of potash. This saline powder, dissolved in water, is to be given every two or three hours (more or less frequently, according to circumstances) in the middle and last stages of fever, and to be gradually left off as the convalescence advances. These salts enter the circulation and do not irritate the stomach and bowels; and according to Dr. Stevens, when given before the stomach has ceased to perform its functions, the bad symptoms soon disappear. A solution of the muriate of soda (two table-spoonfuls to a pint and a half of tepid water or thin gruel) may also be occasionally thrown into the bowels. The strength is at the same time to be supported by strong clear beef-tea.

In extreme cases, or when the practitioner is not called in till the very last stage of fever, Dr. Stevens thinks life may be occasionally saved by injecting a saline solution into the veins.

We have lately adopted this saline treatment in some cases of typhous fever. Our individual experience, however, has been so limited that we are scarcely competent to pronounce an opinion on its value. If the premises advanced by Dr. Stevens be correct, (and we have already expressed our belief that a certain class of fevers do originate in a mor-

bid state of the blood,) the saline treatment he has had the merit of proposing, appears the most likely to correct the vitiated condition of the blood. It should also be observed that Dr. Stevens does not overlook the changes in the solids: when these exist, they are to be treated by active measures, and the saline treatment afterwards adopted.

It would appear, also, that the nitrate of potash, which has been long used as a cooling remedy in fever, may act beneficially on another principle—that of altering the diseased properties of the blood.

It is well known that this salt, when mixed with dark blood out of the body, possesses the power of instantly changing the colour to a bright red; and from its having been used with the most beneficial effects in cases of scurvy, it is reasonable to suppose that it will effect a beneficial change in the blood in malignant fever.

It is proper to add a few observations on the diet of fever patients. The complete disrelish of every kind of food during fever points out the necessity of abstinence; and in cases where, from mistaken views of the supposed advantage of nourishment, food of an improper description is given, the stomach frequently rejects it.

For the first few days the patient generally refuses any kind of food. While the febrile symptoms continue, farinaceous substances, such as the different kinds of gruels—arrow-root, sago, rice, prepared barley, and oatmeal, acidulated with lemon juice, form the most suitable nourishment. A cup of any of these gruels may be given at intervals, and if the patient retain the relish for it, a cup of weak black tea may also be allowed occasionally. We have often observed that thirst is more effectually allayed by weak tea than by any other beverage. Sometimes ripe fruits are grateful, and therefore may be allowed in great moderation, unless there be symptoms of gastric disorder, or such fruits disagree.

When the symptoms of fever abate, more particularly when the tongue begins to clean, and the appetite to improve, a portion of stale bread or water biscuit should constitute the only additional nourishment, till the fever has entirely disappeared. The weak animal broths may then be substituted for the farinaceous food; and of these the quantity should at first be moderate, that the stomach may not be oppressed.

In the course of three or four days a little solid animal food, plainly dressed, may be allowed, unless there be special circumstances to forbid it. The quantity of animal food should not exceed three ounces at first, and mutton, from its being more easily digested, should be preferred. If the patient feel any uneasiness after it has been taken, it must of course be omitted, and beef-tea or mutton-broth again for a time substituted.

When the patient has been much reduced, more particularly if there be a natural delicacy of habit, one or two glasses of sherry wine,

mixed with water, may be taken during the day; but, in general, in convalescence from common epidemic fever, wine or fermented liquors are not required, unless the powers are feeble, or the patient has been accustomed to their daily use. As a general rule, nourishment may be given more early in typhus than in the acute forms of fever.

Of convalescence.—In no form of acute disease is the management of convalescence of more importance than in continued fever; and few persons among the educated—none among the ignorant—can conceive the precision that is required in this particular.

It is too commonly imagined that, when the fever has disappeared, all danger is at an end; that nothing remains to be done but to recruit the strength by nourishing food and imprudent exertion. If the feeble state of every organ in the body, but more especially of those which may have been more seriously affected, and the slow and gradual manner in which they recover their natural vigour, were considered, few would be so careless of their safety as to hazard a relapse which might be fatal.

It is the duty of medical attendants to place these circumstances strongly before the patient, and to impress on the mind the paramount necessity of refraining from every thing that is likely to produce excitement.

In almost every case the practitioner has to contend against the prevailing notion, that the strength can only be restored by nourishment, and even wine. The inherent restorative powers of the system, and the greater safety of leaving nature slowly to effect her own purposes, than to hazard a renewal of the febrile action, or to rekindle local inflammation by acts of imprudence, should be pointed out. When the symptoms have been severe, and consequently the treatment active, more especially when large losses of blood have been sustained, the greater is the danger of relapse. In some instances again, the local inflammation which may have arisen has not been wholly extinguished, there is a lurking indisposition—a tedious recovery, as it is termed. Such cases, it should be remembered, only require the excitement resulting from indiscretion in diet or prolonged exertion, to reproduce the local inflammation.

In the management of convalescence, therefore, the patient should not be permitted to sit out of bed till the strength be considerably advanced. It is better that restriction should be imposed a little too long, than that any risk of relapse should be run.

The next point is of still greater consequence—the proper regulation of the diet. This has been already minutely discussed, as well as the order in which the food should be changed. We may, however, remark that, in our experience, by far the greater number of cases of relapse take place from indiscretion in diet. It should also be strongly impressed on the convalescent, that it is as necessary to guard against the quantity as the quality of food, particularly when there has

been gastric irritation in the progress of the fever. The stomach may be able to digest and assimilate a limited proportion of food; but the indulgence of an extra ounce or two may induce oppression, and a renewal of the fever. This organ in convalescence partakes of the external or muscular debility, and the convalescent may as well expect to be able to carry a heavy load on his shoulders, as to digest an undue quantity of food, even of a suitable kind. Indeed, every practitioner of experience knows, that with the best precautions, the return to solid animal food is hazardous.

Besides avoiding every source of general excitement, it is necessary to impose restrictions according as the several organs may have been affected. Thus, when the symptoms in the brain have been severe, undue mental effort should at first be abstained from as much as possible. When the lungs have been inflamed, every circumstance likely to produce recurrence of the pulmonary disease must be avoided; and similar precautions, but more especially with regard to diet, are necessary when the gastric organs have been implicated.

Exposure to cold in the winter and spring must be most attentively guarded against. Many persons who have struggled through a most dangerous fever, have, from imprudent exposure to cold, been seized with intense inflammation in some organ, which has rapidly destroyed life: hence the necessity of suitable clothing, and regulating the temperature of the chamber, during the period of convalescence from fever.

(*A. Tweedie.*)

FEVER, EPIDEMIC GASTRIC. The arrangement of febrile diseases by Sydenham was founded on the observation that such diseases, revolving in cycles, present characters which are probably owing to certain changes in the constitution of the inhabitants of a country, whether produced by the nature of seasons, or of exhalations from the ground, or of food, or by moral causes, or by a combination of all these important influences. These influences, although they act in a manner hitherto unexplained, give a stamp to epidemics; and not only do they affect the epidemic, the great current disease, but also those concurrent diseases which specifically differ from it, while they retain towards it a certain generic affinity. Hence it is that we have considered a passage in Sydenham, which has often been quoted, as the best clue to guide the physician who means to explore the labyrinth of febrile diseases; a passage which, had it stood as a solitary fragment, would have vindicated the claim of Sydenham to be considered a master in the science which he cultivated. So admirable is it, that in letters of gold it ought to be inscribed in the consulting-room of every fever hospital in the empire, to guard physicians against the evils which flow from adopting the exclusive views of systematic writers, or fol-

lowing the dangerous routine of practice to which they often lead. "This, however, I am convinced of from numerous careful observations, that the same method which cures in the middle of the year may possibly prove destructive at the conclusion of it; and when I had once happily fallen upon a genuine method of treating any species of fever suitably to its nature, I always proved successful (proper regard being had to the constitution, age, and other particular circumstances of the patient,) till that species became extinct, and a new one arose, when I was again doubtful how to proceed, and notwithstanding the utmost caution could scarce ever preserve my first patients from danger till I had thoroughly investigated the nature of the distemper, and then I proceeded in a direct and safer way to the cure."

Three times in the course of thirty years, gastric fever, or rather gastro-enteric fever, has prevailed under our observation; first, about the latter end of the last century or beginning of the present, in 1799 or 1800; again in 1816, and a third time in 1826-27. With respect to the duration of its first visit, we cannot speak with certainty; in 1816 it did not continue for many months; but the epidemic which arose in 1826-27 is not yet over: and thus it has afforded to the medical observer an opportunity of deliberately enquiring into its character and tendencies. It is chiefly from this epidemic that the following history of the disease is drawn up.

The following may be considered as the most remarkable features of gastric fever. General uneasiness and restlessness, or, as the patient is apt to describe his condition, "complete wretchedness;" a most unpleasant state of the mouth—a taste which, like the general unhappiness, cannot be described, but is intolerable; heat, often tenderness, or even pain in the epigastrium, and redness of the fauces, which often ends in an aphthous state of that surface.

This species of fever often begins in an unusual manner, and also follows an unusual course. Many patients have fallen under our notice who had been indisposed for a considerable length of time before the formal invasion of the disease; from one to five weeks: they had complained of occasional headache, languor, and irregularity of the bowels; their tongue being white, their stomach flatulent, the eructations fetid; yet were they not without appetite, nor were they by disease incapacitated for business, nor unable to take exercise, although it soon produced exhaustion. Seldom can the day upon which the fever commenced be ascertained, and generally there is no regular crisis; in short, both the attack and the recession of the disease are almost insensible, the former especially often occurring without the consciousness of the patient or the observation of his friends.

Many patients also continue for a long time unconscious of their true state, and are astounded when they learn that they are under the influence of continued fever. During the

years 1828 and 1829 the writer has often found in his study, waiting his return home, a patient who was under an impression that he had contracted some slight disorder of the stomach or biliary organs, but who in reality laboured under gastric fever, and had done so for many days, or perhaps weeks. In these individuals the tongue was generally white, while there was a blush of inflammation in the fauces; they complained of an unpleasant taste, and a degree of thirst: their pulse was from fifteen to thirty beats quicker than natural, and there existed some heat of skin. They admitted that they felt uneasiness in the abdomen, and they complained of restless nights, during which their thoughts were often confused and incoherent, and yet their muscular strength was not much impaired; and hence it was not surprising that they should have expressed no small astonishment when the nature of their illness, with the necessity of confinement to the house, was explained to them. Some were affected with headach, which completely intermitted in the morning, and was severe towards night; and this had been the case for many days before a rigor, which often introduced a state of aggravated suffering, took place. An apothecary of discrimination, explaining the case of a patient who for several weeks had been ill, added that he had been "affected with one of those walking fevers," by which he meant that he had walked about performing his business, while affected with gastric fever.

The tongue in some cases is not loaded; nay, on a cursory examination, one would often be tempted to say that the tongue was quite natural in appearance; for, although the papillæ were elongated, and the intervals between them rather glassy, it was not white, and there was scarcely any coating upon it. But in other cases the tongue is covered with a thick cream-coloured secretion, like size laid on with a brush, and so also are the fauces. This, which resembles the thrush of infants, is one of the most characteristic symptoms of the disease. We once conceived that the appearance in the fauces was caused by exfoliation of the epidermis of the mucous coat, but it is not so; for when the crust is spontaneously detached or removed by a borax gargle, or rubbed off by means of lint at the end of a probe, the surface beneath, although vascular, is not excoriated. Sometimes the coating on the tongue is dry and brown, and sometimes the centre of the tongue appears as if covered with silver paper, the edges being moist. In the advanced stage of the severe cases it is often rough, dry, shrivelled; sometimes it seems as if covered with varnish, and cleft, especially by a central line, these ragades being deep and painful, and leaving permanent furrows.

There is very generally an affection of the stomach, which varies much in severity; so slight is it in some cases that the appetite for food is scarcely impaired, while in others symptoms of intense gastritis are observed:

nor is there any want of intermediate cases of every degree. Generally accompanying the very disagreeable taste already alluded to, there exists nausea and a loose state of the bowels; the stools being watery, of a light brownish yellow colour, and of a pungent odour, not unlike the odour which sometimes exhales from the discharges which take place during dysentery, or like the smell of the steam which arises when *corned* meat tending to putrescency is boiling: these stools are not unfrequently mixed with mucus. Sometimes large discharges of blood from the intestines take place, which generally are followed by a mitigation of all the symptoms of the disease, the blood being generally fetid and dark, almost as dark and much more fetid than the discharges in *melæna*. After such discharges, however, the patient will often sink and die. The urine is mostly high coloured: great thirst usually exists. In a protracted case of gastric fever, a patient attended by the writer drank fifty dozens of soda water. Considerable heat of surface exists, especially towards evening. The pulse varies; its most usual property is hardness: often it will for a great many weeks exceed 120, while in many cases it never exceeds 80: even then the other symptoms are alarming; as, for instance, when the stools and urine are passed involuntarily. Sometimes the disease ends fatally without any tenderness, pain, or inflation of the abdomen; but frequently, as the disease advances, the intestines become distended with flatus, and tympany occurs, which in this disease is a more alarming symptom than it is in most other febrile disorders. And sometimes also in its advanced stages, this variety of fever is attended with stupor, low muttering delirium, hiccup, subsultus tendinum, floccitation: in short, with all those symptoms, bootless to enumerate, which attend typhoid fevers. Moreover the fever is often attended with bronchitis, which gains the ascendancy over the proper symptoms of the disease, and sometimes appears to be the cause of the patient's death.

There is great variety in the state of suffering. Some individuals appear to be scarcely conscious of illness, while very many are miserably wretched and impatient, passing their nights in a state of unhappy and discontented delirium, and declaring themselves ineffably wretched, and in the early period of the disorder are liable to acute headach, which closely resembles intermittent hemicrania: in truth, the disease is often productive of a degree of suffering which is not often exceeded.

There is often a remission of the symptoms after midnight, which continues until morning, when the heat becomes inconsiderable and the extremities cold; then an exacerbation takes place, and the febrile symptoms increase as the day advances: in the evening they are most severe. There is often an aggravation of suffering on every alternate day, the disease being as it were a tertian remittent: the type is not very distinctly marked, yet it is sufficient to lead the attendant to ob-

serve that a good day and a bad day regularly succeed each other.

In females symptoms of hysteria are often manifest during gastric fever, such as attacks of faintness, palpitation, sobbing, pale urine being passed in profusion.

We would remark with respect to these symptoms, when they are discovered in this or any species of continued fever, that they enhance the perils to which the patient is exposed; whereas when hysteria is an adjunct to any other disease, we are led to subtract from the estimate which we might otherwise have formed of the amount of the danger.

In successive seasons we may remark a considerable variety in the symptoms of the fever; for example, the state of the surface of the body varies considerably. For two or three years, from 1827 to 1829, there was an entire absence of eruption of the skin, with the exception of the white miliary rash, which in many patients was to be found in the hollow above and below the clavicle, and in the sides of the thorax over the false ribs. This rash, probably, belongs to the gastric more than to any other species of fever; we do not include rheumatic fever, whether common or puerperal, which has its own miliary rash, but limit this observation to epidemic fevers. During the first quarter of the present century, the miliary eruption was very rare; with a slight exception during all that time, the miliary rash was nearly absent. During the last five, but more especially during the last three years, the miliary vesicle has been very common. During the winter of 1830, if the red miliary rash be papulæ, with minute suppurating heads, that eruption was observed; about the same time petechial eruptions re-appeared (after an absence of several years) as symptomatic of the fever under consideration: the petechiæ, however, were rather clear, diffused maculæ than the florid or purple stigmata, to which, perhaps, the term ought to be limited.

No precise duration can be assigned to gastric fever. We have seen it observe a septenary period, although obscurely. Sometimes it extends not beyond one week; we have known it exist for three months, but its course is sometimes even much more extended. It is exceedingly under the influence of regimen. When pursuing its course silently and unobserved, it may be roused so as to be attended with both suffering and great danger by stimulating ingesta, fatigue, or anxiety. In like manner, also, relapses are very often produced.

There is much obscurity with respect to the infectiousness of gastric fever. To us it has appeared that this species of fever is sometimes infectious and sometimes not. For several years the fever appeared in families only in solitary instances, or if more than one were affected, they were seized nearly at the same time; but it did not extend so as to lead us to think that it propagated itself. We were unable to assign the cause of the disease further than that we observed, in several houses in which our

patients lay, that fetor which is discoverable when a sewer is choked, and in some instances upon inquiry it was found that the sewer leading from the house had been improperly constructed and neglected. In one patient the disease commenced in the middle of the Atlantic Ocean, and a fortnight before he reached land. But it would not be safe to affirm that in the winter of 1830 the fever did not possess an infectious property; in virtue of which, and exclusive of every endemic influence, it spread through families. Thus the family of a gentleman of fortune, part of them from England and part from Ireland, met in the latter end of autumn in a large mansion in the most airy part of the city of Dublin. One of the young people from the country of Cork, who had been indisposed for several weeks, was obliged to betake himself to bed shortly after his arrival; then one of his sisters fell ill, then a second; then a footman who had attended his young master; then a housemaid; then a third sister; then a brother; then a fourth sister; and lastly a fifth and sixth sister, both of whom had come from England during the confinement of the first patient. These individuals were sickening in succession during a period of upwards of three months, and the cases differed only in severity. One of the patients, the footman, died, and the eldest of the young ladies did not require to go to bed; yet were the symptoms of the same kind in all these cases. Many instances of the extension of this fever in families occurred within our observation during the winter of 1830 and 1831, which, although not so conclusive as that just related, induced us to think that gastric fever is sometimes an infectious disease.

This disease depends upon an excited state of the stomach and intestines, which would seem to have been inflamed; but this state is by no means identical with common inflammation. After death, the mucous membrane of the stomach is found thickened, unusually vascular, in many places of a bright or deep red colour, sometimes with blood effused underneath; the vascularity of this membrane is often rather that which would indicate congestion in the veins than in the arteries. There are, however, cases in which ulceration and even perforation of all the coats of the intestines have taken place.

The following case and dissection will illustrate many of the foregoing observations:—W. V., who had been ill for many days, was visited by his medical attendant for the first time on the 13th of November, 1829. He had a sunken expression, his face was covered with perspiration, pulse 120, and weak. He complained of pain in the back of the neck and head, which was removed by some mild opening medicine, and never returned. For the next four weeks he was confined to the house, and engaged in business, which harassed him much. He had all the time the same expression of countenance, a strong tendency to perspiration, particularly after the smallest

dose of antimonial or Dover's powder. His bowels were at all times very free, having three or four evacuations every day without medicine; his sleep was without refreshment; his appetite at first unimpaired; his tongue morbidly clean; his pulse quick and tolerably firm; he chiefly complained of debility, and never of the smallest pain in any part of the body. During the last ten days of his life he was confined to bed. About the 12th of December he became slightly delirious, but still was sufficiently collected to know every one about him, and occasionally to speak on business. He was sunk in strength, his pulse was quick and weak, tongue dry and chappy, great thirst; two or three times he vomited a small quantity of fluid the colour of verdigris. On the morning of the 14th he had a profuse discharge of blood per anum, when he became nearly exhausted; his face was covered with a clammy sweat, extremities cold, and pulse at the wrist imperceptible. Involuntary discharges of clotted blood, slight tenderness of the abdomen—death.

Throughout the attack, medicine appeared to exert too powerful an influence. A few grains of rhubarb produced numerous fluid stools; a few grains of Dover's powder occasioned profuse perspiration. On one occasion he got a little quinine, which disagreed and was discontinued.

Dissection twenty-four hours after death.—On opening the abdomen a great quantity of the same kind of fluid which he had passed per anum flowed out and ran about the floor. The intestines were largely distended with flatus of insufferable fetor. The liver was of a dark green colour; the gall-bladder greatly distended with bile. The lesser omentum was black and gangrenous; its structure giving way under the finger. The stomach of the usual size. On opening it, the mucous membrane presented a singular appearance; it was thickly coated with lymph, which appeared in masses resembling small glands, of the size of half a split pea: towards the cardiac orifice and at the greater extremity of the stomach, the surface was very dark-coloured, almost black, and had much the appearance of gangrene. There was a large ulcer, of more than the size of a shilling, which penetrated through the substance of the stomach; its edges were thick, elevated, and rough on the internal side, more smooth on the peritoneal side, but still thickened; the viscus appeared more healthy towards the pylorus, which was greatly contracted in size, and scarcely permitted the passage of the little finger. Along the tract of the lesser intestines very vascular patches were observable on the peritoneal surface. A portion of the intestine close to the termination of the ileum, about eight inches in length, was removed and slit open. On the mucous surface there were seven or eight ulcers, elevated at the edges and hard. One of them was sloughy, and penetrated through all the coats of the intestine into the cavity of the peritoneum; the surface was smeared with the same kind of bloody

fluid already mentioned. The great omentum was thickened, of a dark mahogany colour, evidently in a state of inflammation approaching to gangrene.

There is one consideration which vindicates the publication of this case of gastric fever, namely, that it illustrates an important peculiarity in the disease. Extensive mischief often takes place in the abdomen without there being any symptom, such as great heat, tenderness, pain, or tumefaction, till within a very short time before death, to indicate that a disorganizing process is going forward.

Treatment.—The morbid action of the mucous coat of the intestines does not terminate as common inflammation does, but produces excessive secretion; yet this increase of secretion does not, at least in the first instance, relieve the irritation of the surface from which it proceeds: frequent copious watery stools are often productive of no relief, and yet they may not safely be checked—we may moderate, but we must not suppress these discharges. If these discharges do not reduce the strength of the patient, if they occur not more than three or four times in the day, the less we do the better. We may prescribe mild glysters, light and nourishing drinks in small quantities, barley or rice water with a little isinglass, or gum-water with syrup of capillaire; we may moderate the heat of the surface by tepid affusion or sponging, equalize the circulation by fomenting the legs, and applying cold water and vinegar to the head: while we ensure ventilation, we must not reduce the temperature of the apartment below fifty degrees; and, finally, we are not to employ internal medicines, whether purgative or astringent, without a very clear indication. In truth there are many cases in which nothing can be done by the physician, but to ascertain, at each successive visit, that there is no aggravation of any of the symptoms of the disease. And yet it is of great importance to recollect that there is no disease in which he is in greater danger of losing the confidence of his patients, unless he explains the probable duration of the fever, and the danger which often suddenly arises even in the mildest cases. In reference to the great proportion of cases in which the practitioner is not required to interfere, the writer cannot help alluding to a physician, originally a man of very energetic measures in the treatment of fever, who, it is said, became, within the last two or three years of his life, remarkable for his "milk and water practice." Now if the physician alluded to was treating the disease under consideration, as there is reason to believe he was, he evinced his skill; for had he in most cases employed either depletory means or stimulants, fewer of his patients probably would have recovered than actually did. Long and watchful practice confers no greater boon than in enabling a physician to be inactive without loss of character, or the danger of being supplanted by those who think it necessary to practice, not only for the benefit of their patients, but on the cre-

dulity of the attendants or friends of their patients.

If the discharges exhale a pungent or fetid odour, we may give charcoal, recently and finely levigated, in doses of fifteen or twenty grains. If the discharges are very frequent or excessive in quantity, they may be checked by means of enemata of laudanum and mucilage. The enema, for an adult, consisting of fifteen or twenty drops of laudanum in two ounces of mucilage of gum-arabic or starch, administered immediately after a stool, and kept from passing off by means of a towel pressed against the anus, will often check the discharge for many hours. In this state of the bowels a quarter or one-fifth of a grain of the watery extract of opium, with two or three grains of rhubarb every fourth or sixth hour, will often be found useful. If, on the contrary, the bowels have ceased to act, and the patient become heavy and oppressed, a mild aperient glyster, gruel with soft sugar, and a small quantity of Glauber's salt, or an aperient draught of the mildest kind, by resuscitating secretion will relieve the whole system from oppression. It is very remarkable in this disease how small a dose of any medicine, whether aperient or astringent, will produce a sensible effect; and hence it would appear highly important, as our object is often merely to avoid extremes, not to give medicines in an overdose.

When the bowels are not in a state to require either purgative or astringent medicines, (and this will very often be the case,) the mineral acids may be given generally with great benefit. The writer has in general preferred the nitro-muriatic acid: two drops of the nitric, and four of the muriatic, in a large wine-glassful of water, may be given every second or third hour; in general this draught will prove not only beneficial, but very agreeable to the palate and feelings of the patient, tending to quench thirst, remove the disagreeable taste, and allay fever and irritability.

As the disease advances, very weak chicken-broth or beef-tea will be useful, and the patient will sometimes require wine, but it must be given very sparingly; an ounce, or even half-an-ounce of claret diluted, and given every third or fourth hour, generally will prove a sufficient quantity, or a tablespoonful of sherry in a little soda water, or one or two table-spoonfuls of Hock or Barsac in Seltzer water. No point of practice more requires to be well considered than the exhibition of wine in this species of fever. There is a species of debility produced by an excited state of the mucous membrane of the stomach which wine will not relieve, but which will yield to topical bleeding; this often attends the earlier part of the disease, when indeed it will very seldom be necessary to give wine; in its more advanced stages, when much exhaustion is complained of, when the pulse is characterized by smallness, irregularity, or inequality, and when the circulation in the extremities is languid, we must give wine, but very cautiously; and we must be prompt in withdrawing the allowance of wine upon any gene-

ral reaction or local determination taking place. There are two principal terminations of fever, one by a change in the distribution of the fluids, the other by those vessels which have been in a state of congestion returning to a more natural condition. In both of these there is increased or altered secretion; in the former, from a part of the system distant from that principally affected; in the latter, often from the affected surface. In catarrhal, gastric, and enteric fevers the disease very generally terminates by secretion from the affected mucous membrane, and the resolution of the disease is almost insensible. Now, as a general rule, it will be found that wine is little needful in this class of fevers; indeed in most of the cases it may altogether be dispensed with.

In gastric fever with a dry tongue and tympanic abdomen, chicken-broth, or Seltzer water with milk, will be preferable to wine; at all events wine ought not to be given at the first appearance of these symptoms. The tympany may often be removed by means of spirit of turpentine, but will generally soon return; and turpentine, at each successive dose, will be found of less and less efficacy. Emollient enemata, terebinthinate fomentations, blisters to the abdomen, nitre largely diluted, from 3℥ to 3i to sixteen or twenty ounces of almond or arabic emulsion, taken in the course of the day, with small doses of rhubarb, was the treatment most applicable to this state. When the tension is removed, wine is sometimes needful, or a tea-spoonful of brandy in a small cupful of warm milk or gruel every three or four hours, may be given with advantage.

When the patient is restless and uneasy, a change of bed will often prove most tranquilizing. When the circumstances of the individual will permit, there ought always to be two beds in the chamber. There ought also to be an easy chair, in which the patient, when able to leave his bed, may sit, half-recumbent, during part of the day; in which position with his legs on a footstool, fomentations may conveniently be applied to the whole of the lower extremities.

Is bleeding requisite in this form of fever? Very often it is. When in a young and healthy patient there is early in the disease much vascular reaction, nothing will prove so useful as the loss of eight or ten ounces of blood; and when tenderness and heat of the abdomen is discovered at any period of the disease, from eight to eighteen leeches may be applied. So also ought we to proceed when there is excessive irritability of the stomach, with unquenchable thirst. But we are not to bleed as if the disease were to be extinguished by bleeding: this it cannot be—we may expect to moderate the severity of the symptoms by bleeding, to restore secretion if it be suspended, to moderate secretion if it be excessive; but as the disease generally has a long course to run, and as the issue will depend upon the strength of the patient being husbanded, if there is nothing in the intestinal tube which indicates inflammatory irritation, our part will be, not to bleed,

but to allow the disease silently to wear itself out, unless in those cases in which inflammation is kindled up in the progress of the fever in other organs, in the lungs for instance, which was often the case while an influenza prevailed in the winter of 1829. In one of many such cases the writer directed 60 ounces of blood to be taken within five days from a lady in the third week of gastric fever, to subdue a bronchitic attack which was superinduced; he has also been obliged to employ the lancet freely in order to relieve encephalitic attacks.

It may not be useless to remark, that within the last ten years the lancet has not been in such requisition as it was during the preceding decade: the fevers in general have had less of an inflammatory character. Irish physicians of the present day who are eminently skilful in the treatment of acute diseases, are almost all eclectics, have no fixed routine of practice, but are equally ready to act with the decision which those dangerous contingencies above alluded to may require, or to remain calm spectators of a distemper which often requires nothing more than the *dieta aquea* from the beginning to the end.

This is not a fever which requires a mercurial every night and a drench of infusion of senna and salts in the morning. It would be most mischievous to give purgatives daily; you thus increase the peristaltic movement, and disturb the bowels when it is of the greatest moment to keep them at rest. There are three points to be attended to in gastric fever, as contra-indications, before we prescribe a purgative: first, the outline of the abdomen—when the ribs are prominent and the belly soft; secondly, the condition of the stomach,—when the stomach is irritable, the patient complaining of nausea and sickness, with tenderness of the epigastrium; thirdly, the quality of the discharges from the bowels—if these be serous or mucous, or rendered such by purgatives, then let us withhold these medicines, or administer them with the utmost caution. The purgatives which the writer generally employed, were rhubarb with manna, phosphate of soda in weak broth, Rochelle salts, or a solution of soda taken with lemon-juice; citrate of magnesia, or sulphate of magnesia in infusion of roses. When there was evident deficiency of bile in the stools, blue pill or quicksilver with magnesia, with or without Dover's powder, in minute quantity, were often prescribed.

The management of the surface of the body is of considerable importance. Every evening, (so long as the patient retains sufficient strength) when the heat of skin and anxiety are greatest, the writer is persuaded, from trials made under his own observation, that the tepid shower-bath will be found a valuable remedy. Tepid fomentations to the limbs, renewed frequently, for at least an hour at a time, two or three times in the day, and especially before the usual time of going to rest, will often remove the febrile irritability and dispose the patient to sleep.

(John Cheyne.)

FEVER, INTERMITTENT, or AGUE.—

This disease may be conveniently considered under the three following general heads:—1. simple or mild intermittent; 2. complicated or malignant intermittent, equivalent to the *fièvres intermittentes pernicieuses* of the French writers, the *febres intermittentes comitatae* of Torti and others, and the *epiala* of Galen; 3. masked intermittent, or the *febres intermittentes larvatae* of authors.

1. *Simple or mild intermittent fever.*—This disease consists of a series of febrile paroxysms recurring at times more or less regular, and alternating with apyrexia nearly if not quite perfect. There is generally but one fit in the space of twenty-four hours.

The time intervening from the commencement of one paroxysm to that of the paroxysm next succeeding is called an *interval*, whilst an *intermission* comprises the period from the cessation of one fit to the beginning of the next.

Ague displays itself under three principal forms, which may be considered as *genera*, if the disease constitute an *order*, as it does in the nosology of Dr. Cullen, or as *species*, if it be considered merely a *genus*. These are—

1. Quotidian, having an interval of twenty-four hours, the accession of the paroxysm being early in the morning.

2. Tertian, having an interval of forty-eight hours, the paroxysms occurring at or about noon.

3. Quartan, with an interval of seventy-two hours, the fit commencing in the afternoon, generally from three till five o'clock.

There are sundry deviations from these leading types, but to narrate them all would be a burden to the attention and memory of the reader without proportionate instruction. It will be sufficient to point out those varieties which are of most frequent occurrence.

The double tertian is very often met with. A paroxysm occurs daily, and hence the disease would naturally be supposed to be quotidian; but on observing its course and comparing the paroxysms, it will be found that those of alternate days only correspond in duration and violence, and that they commence about noon. It appears as if the fits of a milder disease were inserted between those of one more severe.

A triple tertian occurs daily with two paroxysms on one day, and on the other one only.

A duplicated tertian returns only on alternate days, but on these days has two paroxysms.

The double quartan has a paroxysm, generally slight and of short duration, on the day succeeding that of the regular quartan recurrence, so that on the third day only is there a perfect intermission.

The duplicated quartan has two paroxysms on the day of attack, with two days of intermission; thus strictly resembling the duplicated tertian, allowance being made for the difference of the primary type.

A triple quartan has a light febrile paroxysm

on each of the days usually allotted to a perfect intermission.

Agues having intervals of five, six, eight, or ten, &c. days' duration are mentioned by authors of repute, but they are acknowledged to be rare. Some of these probably belong to the ordinary types of the disease, and either by the effect of medicines or some spontaneous change in the constitution certain paroxysms appear to be presented, and hence arises the duration of the intermission. Others do not admit of explanation on this principle, but are really what they appear to be, intermittent diseases recurring at intervals of many days; but these are much more frequently masked intermittents, (that is, the symptoms of other diseases, such as hemicrania and various neuralgiæ, or even apoplexy, returning periodically,) than regular agues.

Of the three primary types, the tertian is by much the most frequently met with; the quartan stands next; whilst the quotidian is in some degree rarer than the latter.

The types frequently pass into each other; but we oftener observe that those whose interval is short assume the more lengthened forms than inversely; for instance, the tendency of quotidians to change into tertians is very great. But the contrary mutation, that of a disease of a long interval into one of a shorter, is often observed, and it denotes the increasing severity of the malady, for it is a remark of Celsus that quartan kills no one, but if it be converted into a quotidian, which it never is but by the fault of the patient or his physician, it is then very dangerous. (Lib. iii. cap. 15.) Intermittents, too, not unfrequently assume the remitting form, and this is occasionally attributable to the untimely employment of certain medicines. We very often observe the contrary order, remittents changing into intermittents, and this is the safer change for the patient, as it shows the diminishing intensity of the disease.

Agues are much more frequent in the spring and autumn than during any other season of the year. Those occurring in the former period are generally tertians and quotidians, and are found to yield readily to remedies, whilst those prevailing during the latter are more intractable; and quartan, the most obstinate form of all, (so much so indeed that it is said by Celsus rarely to terminate before the following spring,) is found to constitute a more considerable proportion of the cases.

Symptoms.—The disease rarely displays itself at once under the form of ague in an individual who has not previously laboured under it. The patient feels indisposed, has headach, weariness, and pains of his limbs, thirst, inappetency, white tongue, frequent pulse, high-coloured urine, and dark discharges from his bowels. This feverish state displays its periodical tendency by well marked exacerbations and remissions, the former generally occurring daily about noon. After this febricula, or fever, for though sometimes slight it is occasionally severe, has endured for a time varying from four days to a fortnight, the patient is seized

with a severe rigor, and the ague which the medical attendant, if experienced in this class of disorders, had been expecting, manifests itself.

The paroxysm commences with a sense of creeping or coldness running down the back, the nails turn blue, the features become pale and shrunk, the skin wears the appearance of what is called goose-skin, and the pulse is small and rapid. The coldness soon becomes general, and amounts to shivering with chattering of the teeth; cough, dyspnoea, and oppression of the præcordia occur; there is a sense of painful constriction round the temples; severe aching in the back; nausea and often vomiting. This, when it occurs, seems to have the effect of bringing on the hot stage more speedily; though, without such an occurrence, it succeeds the first stage after it has lasted for a period varying generally from half an hour to two hours and a half. The hot stage is denoted by great heat of the surface, a forcible pulse, intense thirst, dry tongue, headach with throbbing of the temples, and scanty and high-coloured urine; in short, by all the indications of an ardent fever. The mean duration of this stage is from three to eight hours. At its close a gentle moisture, which soon amounts to a profuse sweat, appears on the skin; the pulse becomes remarkably full without losing much of its frequency; the head-ach and thirst subside; the urine, which during the cold stage had been deficient, pale, and limpid, and in the period of excitement had almost ceased to be secreted, is discharged copiously, and deposits a lateritious sediment; and the bowels are either evacuated spontaneously or are readily amenable to cathartic medicine. At the termination of the sweating process the patient feels as if restored to health, a sense of exhaustion excepted. On the following morning, should the case prove a quotidian, about noon of the third day, if a tertian, and in the afternoon of the fourth, should the disease be a quartan, the coldness again commences, and there is a repetition of the symptoms which have just been described.

The duration of a paroxysm varies in the different types. It will be very near the truth to estimate the mean length of the whole paroxysm of a quotidian at sixteen hours, whilst a fit of tertian completes its stages in ten hours, and a quartan in six, of which fully two are occupied by the cold stage. Any considerable excess beyond these periods constitutes a protracted paroxysm of the respective diseases. When this protraction takes place in a quotidian, it is manifest that there can be little or no intermission, and most modern observers would perhaps term such a disease remittent fever, between which and intermittent the boundary line is often very faint. The Greek writers named it *amphemerina* and the Latins *quotidiana continua*.

The paroxysms of all the forms are apt to vary the time of their recurrence, that is, to commence at an hour somewhat earlier or later than those which preceded them. It may be

remarked that retarding are generally to be preferred to anticipating fits, the former showing the power of medicinal agents over the disease, the latter that it is still uncontrolled.

Though it appears certain that ague, like other febrile diseases, has a tendency to undergo a spontaneous cure, or, as it is expressed, to wear itself out, yet this disposition is counteracted by so many circumstances, and our opportunities of witnessing the unassisted power of the constitution over any disease are in the present day so rare, that it is impossible for us to give from observation any suggestion as to the time generally required for this natural cessation. The ancients, whose opportunities of estimating the unaided or imperfectly aided influence of nature over disease were infinitely greater than ours, give us little more information on this point than that already quoted from Celsus, and which has frequently been confirmed by others, that quartans, which generally commence in autumn, rarely cease till spring, and an intimation that a tertian *might* cease spontaneously, or at least without the employment of anti-periodic remedies which they were ignorant of, at the third paroxysm.* It has sometimes, though but rarely, occurred to the writer to see quotidian and tertians cease without the employment of any remedies of that description, after three or four fits, the cessation coinciding with the appearance of an abundant herpes labialis, an appearance always of the best omen in this class of diseases, whether intermittent or remittent. But he has never observed this in quartans, which are much less yielding than the other forms of the disease, and are more frequently complicated with those visceral affections which, from being effects of the disease, become its perpetuating causes, and invest it with a character of great obstinacy. These complications, it must be remarked, not unfrequently occur in the course of tertians and quotidians, and render them intractable, but they are less essentially a part of them than of quartans.

The tendency to relapse is great, and it is very apt to take place on the days corresponding to that of the paroxysm; and hence great caution should be observed after the interruption of the disease, as to avoiding exposure to cold and fatigue, and respecting diet, particularly on these days. A gentleman who had recovered from ague had a relapse at Lisbon from drinking a glass of iced lemonade on the day corresponding to the tertian period, which was the form he had laboured under. Causes apparently slight may occasion a recurrence of the disease at periods so remote that the term relapse would scarcely be applicable. The late Dr. Gregory of Edinburgh was in the habit of relating in his lectures the case of a young West Indian, who, having at some former period suffered under ague, struck his shin against the scraper in going into the classroom of the Institutes of Medicine, and had immediately a paroxysm of the disease. The

writer was stationed at Canterbury in August, 1814, with the corps of cavalry of which he then had medical charge, and which had recently returned from the Peninsula, where very many of the officers and soldiers, perhaps the majority, had laboured under ague. The wind set in suddenly and coldly from the east, and immediately his hospital, in which for months there had been no cases of the disease, was filled with intermittents.

Complications and sequela of the disease.—

It may appear inconsistent to speak in the present department of complications, but it is intended that only such lesions of structure shall be noticed here as result from a long continuance of a mild disease, those dangerous organic changes which are almost essential to the nature of malignant intermittent being reserved for future notice. The tendency of the simplest kind of intermittent to affect the viscera of the abdomen is very great, as is shown by the following fact: if any cathartic be given to a patient immediately after even his first fit of ague, a quantity of dark bilious matter is discharged from his bowels. During the cold stage the blood seems to be largely accumulated in the veins of the viscera generally, and very much so in those of the portal system, so that we find the functions of the alimentary canal and the liver disturbed early in the disease; and merely by its long continuance, even should its general character be devoid of all malignancy, serious organic affections are occasionally produced. That the accumulation of blood in the viscera during the cold stage is considerably instrumental in engendering them, is shewn not only by general reasoning of a very obvious nature, but by the fact that these morbid affections arise more frequently in the quartan, which has the longest cold stage, than in the other forms of intermittent. The following case may serve to illustrate the effect of venous accumulation in generating structural changes. It once occurred to the writer to see a person die in what appeared to be the cold stage of a first fit of ague. Heat applied in various modes, ammonia, ardent spirits, ether, and other stimulants, failed to bring on reaction. He lay as cold as marble, and shivering violently, without any pulse at the wrist, and his heart acting very feebly for eighteen hours, and then expired, his intellect remaining unclouded till within a few minutes of his dissolution. The principal morbid appearance discovered was in the liver. This viscus was very much enlarged, and extending below the cartilages of the ribs towards the umbilicus, had a lobulated appearance, and was gorged with blood; it seemed, indeed, as though it had yielded in those few hours to the pressure of the fluid which distended its vessels. The man had not previously complained of indisposition, but had undergone cheerfully the toils of the Peninsular war, performing his duty as groom to an officer.

To this cause, the remora of blood in the veins of the viscera during the cold stage, is

* Lib. iii. cap. 14.

superadded the *arterial* congestion of the same organs during the stage of excitement; the word congestion, which it must be observed has been used in various senses, being here employed in the signification, now we believe the most usual, of determination of blood, a part of the state of inflammation, but which may exist independent of it, though its long continuance or frequent repetition has a tendency to induce it.

The disposition to these affections of the abdominal viscera is early displayed by a furred state of the tongue and a considerable degree of epigastric tenderness increased by pressure. They are occasionally fully formed during the persistence of a long-continued intermittent, and sometimes, their rudiments being then laid, they attain a fuller development after it has ceased or been subdued by medicine, especially if the patient remain in the climate where the disease commenced. Their existence is indicated by the following signs. The countenance of the patient is pale and bloodless, and if the disease be of some standing, appears puffed and œdematous; occasionally it has a yellow tinge, and yellowness is almost always perceptible in the conjunctivæ; there is great debility, and the patient is breathless on slight exertions; the epigastrium and both hypochondria appear and feel full and distended, and are tender on pressure, but independently of pressure there is a sense rather of weight than of pain, or at most of very obscure pain extending from the epigastrium to the spine. Pain or aching is experienced, too, about the right shoulder or shoulder-blade. The discharges from the bowels are found to be clayey; the urine is high-coloured, with occasionally a jaundiced stain; the tongue has the exanguious appearance of the countenance and is covered with a white or cream-coloured fur; and the pulse is generally small, feeble, and frequent. If these symptoms remain unsubdued or undiminished, diarrhœa or more frequently chronic dysentery and general dropsy supervene, and finally death closes the scene, though generally at a long interval from the commencement of the disease.

In many cases, instead of this complicated state of derangement, in which the spleen, liver, and occasionally the pancreas are involved, we find an affection of the first of these organs only, constituting what is commonly called *ague-cake*. This is denoted by a hard swelling in the left hypochondrium, always indolent at first, and sometimes remaining very long so, and influencing little the general health; but occasionally attaining a great size, becoming extremely painful, and, in climates warmer and more infested with intermittents than our own, inducing rapid death by rupture of the organ.

Persons labouring under these enlarged spleens are observed to be very subject to foul ulcers of the legs.*

Post-mortem appearances.—The milder form of the disease we are now considering is fatal only by means of the consequences of its long continuance which have just been described. The morbid changes generally discovered in fatal cases are, the cellular membrane and serous lining of the cavities distended with fluid, and organic disease in the liver, spleen, and intestines.

The change discovered in the liver consists frequently of augmentation of the bulk of the organ and of the density of its texture, as if from interstitial deposition. In other cases its consistence is diminished, the whole organ appearing to be converted into a dark-coloured pulp resembling a mixture of effused and coagulated blood and shreds of membranous matter. Both the indurated and the softened state are sometimes found co-existing with tubercles dispersed through the viscus. Occasionally the texture is merely more friable than natural, not in the extremely softened state mentioned, and contains small and detached purulent deposits. The only change discovered is sometimes in the bulk of the organ, the texture remaining natural, as in a case related by Grottonelli, in which it had acquired such a size as completely to mask the stomach and intestines, the left portion extending into the left hypochondrium and adhering to the spleen, so that it could not be separated without tearing, the substance being nevertheless perfectly sound.*

The spleen is often found much enlarged, sometimes to quadruple its natural size, and to the weight of six or eight pounds. Morgagni, indeed, mentions a case in which it attained the weight of eight pounds and a half, and occupied nearly the whole of the left side of the abdomen.† Such enlargements coexist with affection of the liver, but, as already stated, are found to be consistent with a healthy condition of that organ. The density of the viscus is occasionally increased; but in the majority of instances its interior texture is remarkably soft, and it becomes evident that the hardness felt in the left hypochondrium before death had arisen from the extreme distention of the tunic of the spleen from the quantity of fluid effused into the organ; and the pain felt in a viscus possessed of little sensibility appears to arise from inflammation of its covering induced by the same distention. This inflammation is often visible after death, the tunica propria being highly injected, as if by art. When the organ is examined, it is hard, tense, and resisting; but on being cut it is found to consist interiorly of fluid, sometimes greyish-black, sometimes having the deep purple of lees of wine, intermixed with mere shreds of fibrous or membranous matter. Should death take place from rupture of the spleen, it is preceded by lancinating pain of the abdo-

† Epist. xxxvi. p. 17.

* Morgagni de Sedibus et Causis, Epist. xxxvi. 18.

men, small and frequent pulse and cold extremities; and on opening the cavity it is found to contain a quantity of dark-coloured fluid which has flowed from the spleen, in which either one or more small crevices, or round and ulcerated apertures, are found. A case is mentioned by Professor Morelli of Pisa, in which an enlarged spleen had contracted an adhesion to the left extremity of the colon, where it turns to form the sigmoid flexure, and its contents had thus been discharged by stool, the patient being supposed to labour under *melæna*. A case is related by M. Gasté in the *Bulletin de la Société Médicale d'Emulation*, in which there was found in the left hypochondrium a large peritoneal pouch circumscribed outwardly, above, and posteriorly by the diaphragm, within by the stomach, and below by a small portion of the colon and the left kidney. This sac contained two pints of a sanies resembling wine-lees, and the spleen occupied the lower part of it. This organ was of its natural size, but its surface was tuberculated, and its concave part displayed several irregular ulcers from half an inch to two inches diameter.

Should dysentery have existed before death, there will be found ulceration of the great intestines.

Remote causes.—The most uniformly operative of these is, unquestionably, malaria; indeed, it may be doubted whether any case of idiopathic intermittent can occur independently of its agency, either as a predisposing or exciting cause. (See *MALARIA*.) Other circumstances may co-operate; an individual, for instance, debilitated by privations of food or sleep, by debauchery or fatigue, is more susceptible of the influence of this poison than one whose strength is unimpaired; and should he be attacked with ague, some of the circumstances enumerated may be considered as the predisposing causes of the disease, and marsh miasmata its *exciting cause*. On the other hand, an individual who has been exposed to the effluvia of swamps, may suffer a fit of ague at once from some trifling circumstance, such as drinking a glass of iced lemonade, (an example of which occurred in the person of the writer,) exposure to cold, &c. when the effluvia should be regarded as the predisposing cause.

Some authors have supposed ague contagious. This was the opinion of Baunarez and Cibot in Spain, Bailly and Audouard in France, and Cleghorn and Fordyce in our own country. Cases have fallen under the writer's observation which have led him to entertain at least a suspicion that such was the fact; but the most forcible case for the affirmative of the question which he has met with is one related by Bailly. "A lady arrived in Paris with an intermitting fever, which she had contracted in the country in a marshy situation. This fever was accompanied by violent vomitings and other serious symptoms, which displayed themselves at every paroxysm, and forced me to give bark. Scarcely was she cured, when her husband,

who had never quitted Paris, but who had had the imprudence not to keep himself apart from her during her illness, was struck with the same symptoms and in a manner altogether similar."

The proximate cause or nature of intermittents will be considered after the symptoms and morbid appearances of the complicated and malignant form have been presented to the reader.

Treatment.—This will be best understood by our examining into the merits of the various remedies employed for the cure of intermittents, and endeavouring to indicate the circumstances of the disease to which they are respectively applicable.

1. *General bloodletting.*—Though frequently useful and often imperiously demanded in the complicated form of the disease, this remedy appears to be one of doubtful value, or even safety in mild intermittent. At the commencement of ague it is very usual to find the intermissions too imperfect to admit of the antiperiodic remedies, such as quinine or arsenical solution, being resorted to for terminating the disease; but antiphlogistic diet, mercurial purgatives with antimonials, and local bleeding to the epigastrium if there be tenderness in that region, will generally suffice, without the assistance of general bleeding, to bring the patient into the condition required for their administration. Should, however, ague in any part of its course be complicated with inflammation, existing, not only during the paroxysm but in the intermission, in such intensity as would under other circumstances indicate the propriety of general bleeding, then it should be employed without hesitation. The writer can state from experience, that cases which had resisted the usual antiperiodic medicines, the disease being kept up by a local inflammation, have been made amenable to their action by bloodletting. But the propriety of practising it indiscriminately as a remedy for ague seems more than questionable; nor, should circumstances render its employment advisable, does it appear to be established that the cold stage of the paroxysm, which is the time selected by Dr. Mackintosh for its employment, possesses any advantage over the intermission, when it is generally performed. The latter period, on the contrary, seems better suited for giving the physician a precise knowledge of the extent of the local disease, and for enabling him to adjust the quantity of blood to the necessity of the case.

The gentleman above-mentioned published, in the 27th and 28th volumes of the *Edinburgh Medical and Surgical Journal*, two papers, advising the employment of this remedy in the cold stage of ague, and containing eight cases illustrative of the efficacy of the practice. Of these cases, four certainly appear to have owed their recovery principally to the bleeding, but in the remaining four the cure was accomplished by quinine; and there is great reason to think that it would have taken place sooner had that remedy been employed earlier,

though the bloodletting had been omitted. The four cases in which the practice was successfully employed were of very long standing; and there is every probability that in them the disease was perpetuated by chronic inflammation of some viscus, though only in the eighth case are the symptoms so detailed as to enable us to fix on the site of the inflammation. In this case it was in the spleen; and all these cases fall under the description of cases to which we have argued that bleeding is applicable. The practice of Dr. Mackintosh, as a general remedy of ague, was subjected to a full and candid trial by Dr. Stokes and Mr. Gill, a narration of which will be found in the 31st volume of the Edinburgh Journal; and if the reader will refer to it, he will probably agree in the sentiment expressed by the former of these gentlemen, that the result is calculated to convey an impression unfavourable to the indiscriminate or even frequent use of bleeding in the cold stage of this disease.

Local bleeding is a safe remedy, and the application of leeches to the epigastrium or either hypochondrium is often of great benefit in the slighter gastric, hepatic, or splenic complications which are so frequently met with, and may be with propriety substituted for general bloodletting in the inflammation of any organ, if not of a sufficient degree to keep up constitutional excitement during the intermission. It may be remarked, too, that there is no inconsistency in these moderate depletory measures being promptly followed or even accompanied by antiperiodic remedies, such as arsenical solution or quinine.

It should be observed that the intermittent fevers of warm countries require and bear more free depletory measures, both local and general, than those of temperate climates. So decidedly is this the case, that many persons familiar with the agues of Rome and Sienna, where they are probably more prevalent than in any part of the world, always commence their treatment by bleeding from the arm.

Purgatives.—These are important remedies in the treatment of this disease, and circumstances counterindicating their employment are of very rare occurrence indeed; a very unusual degree of debility alone forbidding their exhibition, should other symptoms render it advisable. Those containing a proportion of calomel, or some milder mercurial preparation, should be preferred, from the tendency which the disease displays to derange the biliary system. It was the writer's practice always to empty the bowels by such a purgative after a paroxysm previously to giving bark or arsenical solution, and to repeat it occasionally throughout the disease if it appeared advisable; and the result generally showed the propriety of the plan. Irritation or even inflammation of the gastro-enteric mucous lining should not be considered a reason for withholding this class of medicines, for the worst cases of ulceration or other disease of this membrane have been found in the practice of those

who abstained from them; and it may be considered as ascertained that their judicious exhibition neither tends to induce such disease nor to aggravate it if existing; though it certainly is possible to excite considerable irritation there by needlessly tormenting the bowels with purgatives.

Emetics.—It is the practice of many medical men to give an emetic at the commencement of the cold stage, or a short time prior to the period of its expected recurrence, provided this be ascertained. Its administration in the first mode has generally the effect of shortening the cold stage, and rendering the whole fit milder; whilst the giving of it before the fit occasionally prevents this altogether, and breaks the catenation of the fever. Its exhibition in either mode should be considered only preparatory to the employment of antiperiodic remedies; but with this view it may be usefully adopted where there is no tenderness of the epigastrium, the existence of which should be considered as counterindicating it.

Mercury.—The use of this mineral should be directed rather to the complications of the disease than to the disease itself. Ague is almost uniformly suspended by mercurial action; but besides that we can in uncomplicated cases generally attain the same object by milder methods, it must be remarked that the cures effected by its agency are rarely permanent, the disease occasionally re-appearing immediately on the cessation of its action, or shortly after. But in the treatment of the gastric and hepatic complications of intermittents it is of great value; and no experienced medical man would withhold it in such cases. Its employment may proceed *pari passu* with that of quinine or other antiperiodic remedies; or the complications being removed, and the recurrence of the paroxysms being suspended by its action, those remedies may be administered as a security against relapse of the primary disease.

The subject would be left imperfect did we not mention the vigorous employment of calomel in intermittent fever by our practitioners in India. They administer it in scrupledoses for one or two nights, giving a purging draught on the following morning to carry off the vitiated secretions; and it is subsequently continued in more moderate doses till the tongue becomes clean, when bark is administered.* By the same authority we are recommended to give a scruple of calomel combined with two grains of opium, to allay the irritability of stomach which so frequently attends the paroxysm.

Opium.—This medicine has been recommended in the treatment of ague from the days of Galen downwards. It may be given either during the intermission, at the very commencement of the fit, or in the hot stage. The first method is that adopted by practitioners who rely upon opium for the cure of the disease.

* Annesley, Sketches of Diseases of India, p. 491, &c.

Its employment in this way is little known in this country, but has obtained considerable notice in France from a memoir published by M. Jourdain* on the potion stibio-opiacée of Peysson, which is a combination of opium and tartar emetic. The inference we should draw from what has been stated of the effect of opium given in this combination, and from what we have seen of its employment in any form during the intermission, is, that it should not supersede the exhibition of the usual antiperiodic medicines, particularly that of quinine. But small doses of opium will even be found a useful addition to preparations of bark or arsenic in ague occurring in irritable habits, and particularly when it is complicated with an irritable stomach. The second mode of giving it, just at the commencement of the cold stage, shortens this stage very much, and renders the whole paroxysm milder; facts of which patients are so conscious that our soldiers in the Peninsular hospitals regularly applied for an ague-draught (sixty drops of laudanum and a drachm of ether) when they saw their nails turning blue, which is generally the first sign of the commencement of a paroxysm. Lind attributed the following good effects to opium given in the hot stage:—1st. It shortened and abated the fit; and this with more certainty than an ounce of bark. 2d. It generally gave a sensible relief to the head, took off the burning heat of the fever, and occasioned a profuse sweat, free from the burning sensation which affects patients sweating in the hot stage. 3d. It often procured a soft and refreshing sleep to a patient tortured in the agonies of the fever, from which he awoke bathed in sweat, and in a great measure free from all complaints. The same experienced physician was of opinion that the employment of opium during the paroxysms tended, by lessening their force and duration, to render the patient less prone to liver-disease and consequent dropsy.

Various other stimulating matters have been given during the cold stage, with the view of abridging it, and of thus cutting short the whole paroxysm. Oil of turpentine, in doses of half an ounce, has been thus administered, and frequently with advantage. The old means of the eating of garlic and swallowing pepper suspended in warm water.† An active principle of the latter article, *piperin*, has been recently adopted by Dr. Meli, of Novara, as a cheap and, as he assures us, a very efficacious substitute for sulphate of quinine. He advises that it should be given in doses nearly the same as those of the sulphate, repeated at intervals of three or four hours during the intermission.

Mechanical means have been recommended for the attainment of the same object, viz.

abridging the cold stage, and diminishing the severity of the whole paroxysm. These are the application of tourniquets or ligatures to the limbs. It is obvious that the effect of a moderately tight tourniquet and of a ligature will be the same, that of detaining the blood in the limbs compressed by them; and certainly the former, which was originally recommended by Mr. Kellie, in Duncan's Medical Commentaries for 1794 and 1797, is the more convenient mode of accomplishing the object. Mr. Kellie informs us that if a tourniquet were applied in the cold fit on one thigh and one arm of opposite sides for two minutes, a mild hot stage was induced, and the patient felt himself quite relieved. The instruments were allowed to remain for about fifteen minutes, and then on their removal the cold symptoms did not return. The same gentleman is of opinion that if the tourniquets be applied previously to the accession of the paroxysm, the cold stage will be entirely prevented, and that whether the cold stage be either shortened or altogether prevented, the following hot stage will be rendered both milder and of shorter duration. This practice is not much employed; but a recent writer, M. Bailly, strongly urges its being adopted in malignant intermittent where there is much to be dreaded from a recurrence of the paroxysm.*

If any explanation can be given of this singular effect from such a proceeding, it must be found in the impediment presented to that afflux of blood to the interior, which forms so important a feature of the cold fit, by its confinement in the extremities.

Antiperiodic medicines.—We shall now consider that important class of medicines which are given during the intermission for the purpose of preventing the recurrence of the fits, and of thus curing the disease. We have named them antiperiodic medicines, because the property of curing diseases which recur periodically seems the only one which is common to all of them. That many of them are tonics is true; but their power over intermittents does not appear to be in proportion to their tonic quality, nor is it well ascertained that all of them possess such a quality. No practitioner employs arsenical solution, one of the most powerful of the class, as a mere tonic, nor does it seem certain that it is one; for to infer that it is so from the fact that it cures ague would be reasoning in a circle, and we are not aware of any other whence it could be drawn. Mr. Jenkinson, who has extended its use to painful affections of the bones, recommends its employment only in those cases in which there are regular intermissions; and hence it would appear that in these diseases too it is as an antiperiodic that it is selected. Upon the whole, it seems proper to designate these medicines by the general term here employed, till a fuller investigation of their nature, and of that of the diseases for

* Journal Général de Médecine, tom. lxxxvi. p. 305, and Bailly Traité de Fièvres Intermittentes, p. 433.

† Lib. iii. cap. 12.

* Traité des Fièvres Intermittentes, p. 451.

which they prove a remedy, gives us more precise ideas on the subject.

Of these remedies, the first in importance is certainly the Peruvian bark. A few years ago, a disquisition on the comparative powers of the different species of this drug, yellow, red, and pale, would have been requisite; but as one substance, sulphate of quinine, unquestionably the most valuable gift which modern chemistry has bestowed on our art, now represents them all in practice, such a disquisition would be superfluous. Those only who were in the habit of treating many cases of ague prior to its introduction, and had often witnessed the disgust, nausea, and vomiting caused by loading a patient's stomach with many ounces of powdered wood, can form an adequate opinion of the benefit conferred on our practice by the introduction of the sulphate; and this opinion should be further enhanced by the consideration that the ligneous matter of the bark is certainly a direct obstacle to the operation of the essential part of the mass, for the sulphate decidedly exceeds the gross bark in febrifuge power, even though the latter be equally retained by the stomach.

Of the sulphate of quinine, which we shall consider as the representative of bark and all its preparations, two grains repeated every three hours, or four grains every six hours, are generally a sufficient dose in a case of either of the more lengthened forms of intermittent; but in one of quotidian it is preferable to give three or four grains every third hour. In a complicated and malignant disease, when a patient's life probably depends upon the prevention of a paroxysm, it is frequently given in much larger doses, those of a scruple, for instance, repeated at short intervals; and should those previously mentioned not subdue the mild form of the disease, they should be increased; but doses of from two to four grains will generally accomplish all that is to be expected from the drug in the uncomplicated intermittent of temperate climates. The medicine may be given either in pills or in a draught in any agreeable cordial water, to which are added a few drops of diluted sulphuric acid, which very much aids the solution of the salt. The employment of the remedy should not cease with the suspension of the paroxysms, but should be continued some days as a security against relapse.

It will be known to the reader that the propriety of promptly curing intermittents by means of bark was the subject of doubt and controversy from the first introduction of this drug, and that the two most distinguished writers on the subject, Sydenham and Ramazzini, have taken different views of it, the latter attributing all the pernicious results of the disease to the remedy, the former vindicating his favourite from similar charges brought against it by his British contemporaries, and ascribing the evils to their more general cause, the long continuance of the intermittent. That the remedy is unjustly charged with the general abdominal obstructions and enlarged spleens which are so

liberally attributed to it, is manifest from the circumstance that individuals so situated that they can procure neither bark nor any remedial assistance for their agues, and in whom consequently the disease follows its course unresisted, as happens to the peasants of the country bordering on the Pontine marshes, have the spleen occasionally occupying almost the whole abdomen; whilst those in whom the disease is promptly and judiciously treated, escape such complications. But it must be remarked that the employment of bark requires discrimination and judgment, and that much injury may be done by the routine practice of "pouring it in," as it is termed. The following circumstances should deter us from administering antiperiodic remedies, and particularly sulphate of quinine—the intermissions being imperfect, and a recent local inflammation. In the former case, should we employ this class of medicines, we run great risk of converting the disease into a dangerous remittent or continued form; we ought therefore, by means of calomel purges, saline medicines, and occasionally topical bleeding, to endeavour to reduce the patient into an apyretic state during the intermission, previously to commencing their employment. Should a recent topical inflammation of some degree of intensity exist, we should at once proceed to subdue it by bleeding general and local, mercurials, &c.; and if the ague remain after its cure, then may the sulphate be administered; but the antiphlogistic means, with mercurials occasionally, remove both the local and general affection; and if the antiperiodic be employed in this case, it is rather with a precautionary view than because it is rendered indispensable by the existing circumstances of the disease. It must be observed that the precautions here impressed on the reader against employing quinine during the persistence of topical inflammation do not apply to those chronic engorgements of the spleen and other abdominal viscera which so frequently exist in persons long subject to ague, and which are uniformly aggravated by every fresh attack of the disease. Were we to delay the cure of the intermittent till the splenic or hepatic engorgement were removed, months or years might be requisite for accomplishing the object; the antiperiodic, therefore, should be administered at once. It may be remarked, too, that occasionally circumstances exist which render it desirable that the tendency to periodical recurrence should be combated at the same time that measures are taking to subdue a pyrexial or inflammatory state, permanent but slight in degree; in which case arsenic, in the form of Fowler's solution, should be employed in preference to sulphate of quinine, as being less exciting: but should there be observed any increase of the general pyrexial state during its administration, it should at once be withdrawn, and the antiphlogistic remedies alone persevered in. Finally, by examining all the evidence on the subject, and observing the effect of remedies on ague, we shall reach the conclusion that the diseases

which have been attributed to bark do not arise from its judicious employment, though they are occasionally owing to its abuse, but in an immense majority of instances are to be ascribed to the severity and long continuance of a malady either imperfectly treated, or which our art was too feeble to subdue.

Arsenical solution is the antiperiodic medicine on which, next to quinine, the most reliance may be placed. An extensive experience leads the writer to give it a general preference over crude bark; but he thinks it inferior to quinine, though under certain circumstances it may supply the place of the latter valuable medicine advantageously. It has already been observed that it may be given in a more inflammatory state of the system than this medicine; and again, should an individual have been cured of ague by the sulphate of quinine or any preparation of bark, and have a relapse, it will often be found that the same medicine will not restore him to health, it having lost its power over the system by familiarity, and some other antiperiodic must be resorted to, especially arsenic. This loss of power by long continuance takes place with respect to all the antiperiodic medicines; and hence arises an advantage from having several, that one of these medicines may be substituted for another which has lost its influence. The one we are now considering, arsenical solution, the writer has given in many hundreds of cases, and has never seen any permanently ill effect arise from it, nor indeed any ill effect but a little nausea and griping, which a diminution of the dose, or the addition to each of a few drops of laudanum, speedily corrected. The dose in which it is generally given is from five to twelve drops every four or six hours during the intermission.

The sulphate of zinc stands next in the order of power among these medicines. The best mode of administering it is in pills composed of the salt, powdered ginger, and conserve, each pill containing three grains of the sulphate; and of these, two may be given three times a day during the intermission, the number being increased to three and subsequently to four, which are as many as the stomach can bear. It is advisable to avoid drinking immediately after them, as it is apt to induce vomiting.

Various bitters, and combinations of them with aromatics, have been tried, and occasionally have proved successful. Quassia, alone or combined with some agreeable aromatic, is the most efficacious of them; but all are inferior to the antiperiodics previously mentioned. An extract of the bark of the olive-tree (*Olea Europea*) has been employed lately in Spain and France, and M. Pallas* gives many cases of cures effected by its means. Salicina, the alkaloid of the willow-

bark, has likewise been tried in France, and it is said with a success equal to that experienced from sulphate of quinine. We cannot give any opinion of the two last-mentioned remedies from observations of our own; but the statements of others lead us to think favourably of their merits.

Treatment of the sequelæ of the disease.—

An important remedy for all forms of such affections, and one without which other means prove but too often unavailing, is a change from the contaminated air in which the disease originated to a more healthy atmosphere; for it were to take a very partial and imperfect view of malaria to regard it merely as the cause of fever. It is a poison of the whole system, generating various diseases, particularly of the abdominal viscera, and aggravating those which are existing, occasionally by the instrumentality of open attacks of intermittent, but not unfrequently by a slower and more insidious contamination of the frame.

We have considered these sequelæ under two forms, viz. the more complicated and dangerous one, in which the liver and other organs participate, and the simpler, in which the spleen, an indolent and, so far as we know, comparatively unimportant organ, is principally if not solely affected; and we shall observe the same order in our remarks on their treatment.

In cases of the former description, topical bleeding, which may be occasionally repeated, from the epigastric and right hypochondriac regions by means of leeches, and subsequently blistering the same parts, will probably be found serviceable. One or two full doses of calomel should be given with some smart purgative, and then mercury in the milder form of hydrargyrum cum cretâ or blue pill, should be administered with or without eccoprotic laxatives according to the state of the bowels. After this course has been continued for some time, and been for some time suspended, the nitro-muriatic bath, or sponging the abdomen with the nitro-muriatic solution, may be resorted to. The waters of Cheltenham or Harrogate are found beneficial after the inflammatory action has been very thoroughly subdued by topical bleeding and mercury. Should dysentery be co-existent with the liver affection, Dover's powder should be conjoined with the mild mercurials; and leeches may be applied along the course of the colon, whilst anodyne, emollient, or gently laxative enemata should be administered. If dropsy exist, the mercurials should be combined with squill; but these are cases which too often mock the best efforts of our art.

If the case be one in which the spleen only is affected, a general bleeding should be performed if the patient's strength admits it; and under all circumstances local bleeding from the left hypochondriac region should be employed and occasionally repeated; whilst counter-irritation from the same region by blisters, setons, or moxas, should be subsequently adopted. Purgatives, which cause

* *Réflexions sur l'Intermittence chez l'homme dans l'état de santé et dans l'état de maladie.* Paris, 1830.

considerable exhalation from the mucous surface of the intestines, are valuable adjuvants to these measures; six or eight grains of compound extract of colocynth, with three or four of antimonial powder nightly, followed in the morning by a proportion of sulphate of magnesia, or other saline purgative, will answer the indication exceedingly well. The diet should be light and antiphlogistic. Should these means fail to subdue the disease, iodine will merit a trial. Mercury, so beneficial in most chronic inflammations, is rarely, if ever, of service in these cases.

Complicated or malignant intermittents.—It is not easy to present a methodical view of diseases so multifarious and variable as these. Their basis is an intermittent, which may be of any of the usual types; but either from the very commencement, or shortly after the attack of ague, some important organ becomes affected with disease, generally of an inflammatory nature, which complicates the original disorder throughout its whole course, subsiding but not entirely ceasing during the intermission, and becoming dangerously aggravated during the paroxysm, when, and especially towards its close, death occurs should the case prove fatal. These intermittents are distinguished from those we have already considered by the complications in the latter being merely the result of their long continuance; whilst in malignant ague they are a part, and the most important and dangerous part, of the disease almost from its commencement. From the other division of these diseases, which we have subsequently to notice, they are distinguished by the circumstance, that in masked intermittents the character of ague is entirely immersed in that of some other disease, occasionally an inflammatory one, more frequently affecting the nervous system, occurring periodically, but without any other mark of ague, excepting perhaps a very slight chill, not at all resembling the full shivering of intermittent.

Examples of dangerous complications of ague were once frequent in this country, when ague itself was a more common disease here than it now is, as we learn from the writings of Sydenham and Morton; and they are still occasionally met with, though very rarely in comparison with their former frequency, or their present prevalence in countries more marshy, and situated under warmer latitudes than our own. The Italian writers down to the present time are rich in observations illustrative of their prevalence and fatality, for many parts of that peninsula, particularly the vicinities of Rome and Sienna, are prolific of intermittents of the most pestilential character.

The brain and its membranes, the viscera of the abdomen and those of the thorax, are the seat of these complications, and in this order we shall consider them, premising that it is so usual for the organs of the different cavities to be simultaneously affected that the line of demarcation will not be very precise; and when we speak of ague complicated with disease of

a set of organs, it will be understood merely that the prominent and dangerous symptoms are attributable to such disease, not that those viscera only are affected.

Affections of the brain and its membranes.

—The affection of these organs sometimes takes place suddenly, without there having been any thing in the previous symptoms of the intermittent to indicate to the patient or his attendants that any peculiar danger was impending. Werlhoff relates that one evening he met a widow-lady in the street, who entreated him to visit her on the following day, as she expected her third paroxysm. He went according to appointment, and found her not only in a severe fit of ague, but in a state of complete immobility and with the stertorous breathing of apoplexy. It was found impossible to arouse her; the pulse became more and more feeble, and she shortly expired.* A similar case is related by Bailly.† Benoit Simonelli entered the hospital of Santo Spirito at Rome, on the 22d of July, 1822, labouring under tertian; on the twenty-third he had a slight paroxysm and took after it two ounces of bark; on the fourth, towards noon, he was walking in the ward and amusing himself with the other patients, when he was suddenly seized with a violent shivering, followed by high fever, during which he had convulsive contraction and flexion of the fore-arm on the arm, and complete coma, and in six hours he expired.

These are examples of fatality supervening rapidly on the first symptoms of malignancy; but it is not unusual for patients to pass through a succession of paroxysms, attended with convulsions and coma, alternating with intermissions, in which the convulsive movements disappear, and the patient is restored to comparative sensibility and intelligence; yet may he ultimately sink under the disease with all the symptoms of apoplexy, should the recurrence of the fits not be prevented. Independent of the complication, the paroxysms of malignant ague wear in all respects the ordinary character, commencing with fully formed rigor succeeded by intense heat, and this again by sweat, in proportion to the copiousness of which is generally the completeness of the apyrexia. But we often see that when intermittent assumes the complicated and malignant form, the cessation of fever at the close of the paroxysms is less perfect than in mild ague; so that many cases which, from the mode in which the disease commenced and the periodical recurrence of rigors, are classed with intermittents, might, from the imperfection of the apyrexia, with equal propriety be referred to remittents. Indeed, it may be remarked of these two orders of diseases, that though the extreme points of the scale are readily distinguishable by the least practised eye, yet the intermediate degrees are so blended that it

* *Observationes de Febribus.* Venet. 1764.

† *Traité des Fièvres Intermittentes Simples et Pernicieuses.*

would be often difficult to say where intermission ceases and remission begins. It is usual too to find, that when the more intense symptoms of malignancy display themselves, the type vacillates; a disease, for instance, which had recurred at the tertian period, assumes the quotidian form, whilst the paroxysms of one originally quotidian are apt to be duplicated.

The symptoms distinctly referrible to the brain and its membranes are of two orders, those of spasm or convulsion, and those of oppression or coma. Of the former there is not merely the ordinary subsultus of fever, but well-marked convulsive movements, such as the rapid contraction of the flexor and extensor muscles of the fore-arm already mentioned, convulsive twitching of the fingers; occasionally tonic spasm of the same parts or of the lower extremities, so that the flexors and extensors being balanced, the members acquire a tetanic rigidity; firm clenching of the lower jaw, and violent rolling or distortion of the eyes. Should both sets of symptoms occur in the same patient, it will generally be found that those of convulsion precede in point of time, though ere the close of the disease they are found co-existing. The signs of diminished sensibility are stupor, from which it is difficult or impossible to rouse the patient; immobility; incapability of swallowing; eyelids wide open; pupils occasionally dilated, sometimes morbidly contracted; pulse sometimes strong and bounding, at others small and feeble, and stertorous breathing.

M. Lallemand would consider the first set of symptoms, those of convulsion, to arise from inflammation of the arachnoid membrane communicating irritation to a healthy brain, or, at least, to one retaining its functions to a certain extent; in the second he would suppose that inflammation of the cerebral substance itself existed. It is certain that convulsive movements are compatible and are indeed generally found co-existing with coma, more or less considerable; but the opinion of M. Lallemand is supported by the facts, that in those cases of comatose intermittent in which there are convulsive movements, the patient is still capable of being roused to a degree of attention and to display some share of sensibility; and that in cases of coma without convulsion, the marks of cerebral inflammation are more considerable than in those in which convulsions existed.

The appearances found in the dissection of these cases are—inflammation of the arachnoid coat, indicated by intense vascular congestion; effusion of serum between the arachnoid and the pia mater; adhesion between these tunics, so that they form but one thick membrane, into the tissue of which blood is effused, occasionally by granulations of the arachnoid, or by its being covered by a false membrane; inflammation of the brain, shewn by the cortical substance being of a deep brown or reddish colour, of which the examiner becomes at once conscious if he have an opportunity of making a comparison with the brain of a patient who has died

from some other disease;* oozing of points of blood in great abundance from the medullary substance on its being incised, or softening of the organ, and effusion of serum in the ventricles and base of the skull.

These changes may be found co-existing with extensive lesions of the liver, stomach, intestines, or spleen, such as are met with in the examination of those dead from ague with abdominal complication, which we are now to consider.

Malignant ague, with abdominal complication.—The symptoms found in this complication are great pain of the abdomen increased by pressure; pain of the loins; vomiting, sometimes uncontrollable, of matters generally bilious, frequently bloody; discharges from the bowels of the same bilious or bloody appearance, or insurmountable obstruction; great sense of internal heat; tongue dry, and of a yellow, brown, or bright red colour; urine scanty, high-coloured, and often jaundiced; occasionally yellowness of the conjunctiva and skin; ardent thirst; frequently hiccup; pulse occasionally full, more frequently small, sharp, and contracted, and towards the close of the disease, feeble and sunk; the heat of skin often very great in the early part of the disease, but after it has continued some time the temperature is low, with lividity of the extremities, and cases are occasionally met with of which great coldness, not merely of the extreme parts, but of the trunk of the body, is a prominent symptom, not only during the rigor but the whole course of the disease: delirium frequently takes place during the paroxysm, and if the disease continue, it may be further complicated with coma or convulsions, the marks of lesion of the brain or its membranes.

On examination after death, extensive lesions of the viscera of the abdomen are discovered, of which the following are of the most frequent occurrence. The mucous lining of the oesophagus towards its lower part is occasionally inflamed, has a granulated appearance, or has a false membrane adhering to it. That of the stomach is thickened and inflamed, being of a colour varying from rose to reddish brown, whilst its mucous follicles are inflamed and so elevated as to resemble a miliary eruption, the follicles having a diameter varying from half a line to a line and a half, and being perfectly smooth, without central aperture. The mucous lining of the intestines presents in general the same deep shade of colour as that of the stomach; the valvulae conniventes are red and swollen, and there is occasionally, but not often, ulceration in the vicinity of the ileo-cæcal valve. The sanguineous injection is not always confined to the lining of the canal, but occasionally affects the muscular and peritoneal coats. Occasionally, and especially in cases in which the alvine discharges have been sanguineous, we find the mucous coat not merely inflamed, but completely impregnated with what appears to be extravasated blood.

* *Bailey*, op. cit. p. 182.

The liver is found so gorged with blood, that its parenchymatous structure is almost entirely lost, the whole organ being little more than a mass of extravasation, and so soft that when an attempt is made to raise it, it is torn in fragments by the hands. This softened state occasionally alternates in the same subject with a tuberculated and harder condition. The ductus choledochus is often thickened by inflammation, and the gall-bladder is occasionally inflamed and lined with fibro-albuminous concretion. The bile it contains is generally as thick and black as tar. The spleen, occasionally weighing six or eight pounds, sometimes of its ordinary volume, resembles a capsule containing blood or a greyish pulp. When the peritoneal surface of the intestines is inflamed, the omentum is generally dark and vascular.

Ague with thoracic complication.—This species of complication is more rare than the abdominal and cerebral affections; but in the intermittents of temperate climates it often occurs, and in them probably rivals, if it does not exceed in frequency, the disorders of the viscera of the other cavities. It may display itself in the form of bronchitis, of inflammation of the pulmonary tissue, or of pleuritis. It is probable that a congested state of the mucous lining of the bronchi, closely allied to inflammation, exists in very many cases, perhaps in all, during the cold fit and the short and anxious respiration which attends it; for the stethoscope has made manifest a strong sonorous *râle* in this stage, which has totally disappeared on the breaking out of perspiration. A similar remark may be made respecting the pulmonary tissue—the congested state of the lung which exists in the cold stage of ague is, as Dr. Stokes has intimated,* closely allied to the first stage of pneumonia; but we should not consider ague to be complicated with either bronchitis or pneumonia, unless the symptoms of one or the other of these affections were persistent through all the stages of the disease, and perceptible in the intermission; though it will be readily understood that these, like other inflammatory complications, must receive considerable increments during the vascular disturbance which attends the paroxysm, and that their general intensity will be increased by each successive fit.

We need not dwell on the phenomena which will be displayed by this complication, it being sufficient to remark that they are those of ague combined with the symptoms of pulmonary catarrh, pneumonia, or pleuritis. In cases of fatality, the lesions of tissue customary in the latter diseases will be discovered, with probably some marks of disease in the viscera of the abdomen, the affections of which it is so usual to find associated with all the other complications of ague.

Treatment.—The indications of cure are, to subdue the local affection, and to prevent the recurrence of the paroxysms, each of which, as has been explained, adds to its intensity. But we

must not expect, in endeavouring to accomplish the first object, that the general system will bear those full depletory measures which are required by an idiopathic local inflammation. Rarely can we proceed beyond one general bleeding, and the topical detraction of blood by cupping or leeches, in our antiphlogistic treatment. The rule furnished long ago by Sydenham for our guidance in the management of epidemics in general, admits of very important application to the treatment of malignant intermittent, that we should endeavour to seize the genius or character of the prevailing disorder, and regulate our measures accordingly; for certain agues—those of some climates, and of different seasons of the same climate—are found to bear depletion better than others. It need scarcely be remarked that our local means should be directed to the head, thorax, or abdomen, according as the viscera of one or other of these cavities is the seat of topical lesion, and, consequently, the source of danger. Blisters to the nape in head-affections, and to the thorax and abdomen when they are the seats of disease, should not be neglected. Calomel should be freely administered, especially where the complication is situated in the head or the abdomen; and in the latter case, should the irritability of the stomach induce vomiting, opium should be conjoined with it. Emetics are rarely admissible, for they will tend to aggravate muco-gastritis, which is so frequent a complication, that perhaps no malignant form of the disease is free from a degree of it.

Whilst these measures are proceeding, or after they have been employed for a short time, antiperiodics, especially the sulphate of quinine, should be administered. If the symptoms permitted delay, it might be advisable in every case to abate the local affection by bleeding, general and topical, and by blisters and mercurials, previously to their exhibition; but in many cases we are under the necessity of deviating from this more scientific plan, and of endeavouring to prevent paroxysms, from which much danger is apprehended, by their early employment. An experienced French writer, M. Pallas, recommends that, in cases of gastrointestinal irritation, each dose of quinine, the antiperiodic he recommends, should be conjoined with a grain of the watery extract of opium. If we succeed in stopping the recurrence of the paroxysms, the local affection, which owed much of its intensity to the increase that took place at every fit, frequently subsides easily without leaving any dangerous lesion of structure; but in other cases it must be acknowledged, though the paroxysms are suspended, the disease proceeds in its fatal course under a complicated continued form. It will be readily understood, as we employ quinine or other antiperiodic medicines for the object of suspending the paroxysms, and not on account of their tonic powers, and as topical antiphlogistic remedies may with propriety accompany such an employment of them, that the diet and general regimen of the patient should, with the exception of those cases in which there is

* Edin. Med. and Surg. Journ. vol. xxxi.

morbid coldness throughout the disease, be perfectly unstimulating.

Proximate cause or nature of ague.—We now reach the most difficult point, that of deciding upon the precise nature of those changes effected in the system by malaria, of which the symptoms of ague are the signs. Of these changes two views are taken, each by a different set of pathologists, similar to those entertained by them respectively of continued fevers. By the one party, the localists, a paroxysm of ague is deemed the sign of an intermitting local inflammation; whilst by the other it is thought to be a fever,—an abstraction if you will,—which is known by certain signs, but with the intimate nature of which we are not fully acquainted; and of which, though it is acknowledged that topical inflammation may accompany or complicate it, such inflammation is not thought to be the very essence and the cause of all its phenomena. We shall present the reader with a brief view of the facts which have furnished arms to the advocates of the respective opinions, with little more of commentary on our own part than is necessary to their being fully understood; leaving him to form the conclusion in a matter, which, now that there is no dispute respecting the treatment of the disease, may be considered rather speculative than practical.

The opponents of the first opinion, that of the localists, remark, that though sanguineous congestions unquestionably exist during the paroxysm of intermittent, and cease at its close, yet it is not easy to conceive actual inflammation, with its general thickening and lesion of tissue, as being thus fugacious. Sanguineous distention is an essential part of inflammation; but if we consider it as constituting the whole of that state, the distinction between congestion and inflammation is at an end, and it would perhaps not be very easy to draw the line between the latter and the occasional condition of the erectile tissue. Besides, if we regard the lesions which are discovered in fatal ague, of which so full an account has been given in the preceding pages, it will be impossible to conceive that such extensive disorganizations should have been produced during the last and fatal paroxysm. It will be evident that the inflammation which operated such changes must have been existing in the parts for a considerable period, and, consequently, that intermitting symptoms ought not to be ascribed to this permanent cause.

The localists appeal from the reasonings of their opponents on the necessary fixity or permanence of inflammation for a period longer than the duration of a fit of ague, to examples of external inflammations, such as ophthalmias and cutaneous affections, of which many are to be found in authors, and particularly in the work of M. Mongellaz.* If these cases are carefully examined, it will be acknowledged that almost all of them are rather examples of the aggravation of inflammation during a paroxysm of

ague, than of actual intermitting inflammations. But it must be allowed that all do not appear to be instances of the former description; but that some cases are mentioned which lead us at least to doubt of the necessary permanence of inflammation during a considerable period. As good an example of this kind as is perhaps to be met with, is given in the lectures of Dr. Elliotson, published in the Medical Gazette, in which the bites of leeches which had been applied to the abdomen on account of a diarrhoea with some tenderness there, became itching and tingling, and red at a certain hour every evening, the patient, a boy, becoming at the same time excited and feverish. There was reason to think that he had been exposed to the influence of malaria, and he was cured by quinine. Allowing a certain degree of force to these cases, we may still be permitted to remark that it is one thing to prove that inflammation may be a fugacious and intermitting affection, and another to show that the phenomena of simple ague arise from an inflammation of this kind, existing we know not where, and disappearing and recurring at intervals; though certain French pathologists, it is true, assure us, but on not very sufficient grounds, that it is seated in the gastro-enteric mucous lining; and it may, besides, be observed that these recurrent external inflammations, if there be no other disease existing in the system, do not produce the perfectly formed symptoms of a fit of ague. From the facts stated respecting the inflammations which attend ague, it appears that the doctrine of the localists requires a more ample and impartial investigation than it has yet received, and the consideration how far a permanent inflammation may manifest its existence only at intervals and periodically, and by the phenomena of a fit of ague, should form an important part of such investigation. The extreme feeling of debility, the pain and giddiness of the head, the aching of the loins, a certain degree of obscurity of the intellectual faculties, and the intense coldness of the surface, favour the opinion that the nervous system is the part primarily instrumental in producing the general symptoms, but how far it is impressed by some local lesion lurking in the frame, remains still to be proved.

Intermittence is, so far as we yet know, an ultimate or unexplained pathological fact. Speculative attempts at its explanation have been offered to the public, and we shall present the reader with that of M. Bailly, because it is founded in some degree on induction from facts, and possesses much more ingenuity than any other, though we acknowledge that it leaves unexplained phenomena, which, if it were successful, it ought to embrace, and reposes in part on an assumption which requires proof. M. Bailly first observes that in situations and seasons in which intermittents affect the human species epidemically, epizooties reign among the lower animals, of which he cites numerous examples; but, however their symptoms may vary in other respects, in one point they all agree, that of being strictly continued—inter-

* Essai sur les irritations intermittentes.

mittence being never observed in the diseases of brutes. M. Bailly then remarks that in the mode in which the actions of life are performed, we differ in one sole circumstance from domestic animals; and in this he conceives that the explanation of the occurrence of intermittents in the human subject is to be found. Animals preserve, during the whole of their existence, sleeping or waking, in all the acts of life, the same horizontal position, and consequently the heart, abdominal viscera, and brain retain the same situation relatively to each other; but man, on the contrary, changes from the vertical to the horizontal position, and consequently in him each nycthemeron (period of one night and day) consists of a succession of excitations or sanguineous congestions, which are felt according as he is in the erect or horizontal position, and according as these organs change their situation relatively to the heart, in the abdominal viscera or the brain. These varying congestions of course constitute the physiological or healthful condition of the generality of persons; but (argues our author) every pathological or morbid state is but the exaggeration of a physiological or natural one. The sanguineous congestion of the digestive organs displays itself in a degree which may be considered morbid in females or other delicate persons, who are either sick on first assuming the erect posture in a morning, or feel a total inaptitude for any occupation till they have taken food; and is well illustrated by that febricula, first described by Ræderer and Wagler, which may be said to constitute the habitual state of many literary and other sedentary persons. This slight disorder manifests itself simply by burning heat of the skin, with little acceleration of the pulse, and during it the patient pursues his accustomed avocations. At night he is either hot and sleepless, or is in a profound but painful and agitated sleep, and in either case feels unrefreshed in the morning; but if he remain in bed, the skin becomes soft, moisture is felt on the surface, in fact a sort of crisis takes place, and he feels tolerably well on the following day; but if he rise before this light sweating stage may have occurred, he remains all that day with a hot and dry skin, his countenance wears an expression of fatigue, his mouth is dry, his limbs are feeble, he feels oppressed, and without having any decided indications of disease, feels equally incapable of thought and action. M. Bailly supposes that this disorder is a gastro-enteric irritation produced by the erect position acting on a delicate and sensitive frame; that the horizontal posture diminishes it, and that if the patient remain so long in this posture as to bring this irritation to the lowest point, the functions of the skin are then restored, and the indisposition is removed temporarily by crisis. MM. Ræderer and Wagler have observed that nothing tends so much to the production of intermittent fever in this delicate class of persons as the suppression of these morning perspirations.

What has been described above, which is in some degree pathological, is but an excess of

what exists in all individuals, and intermittent fever is but a further grade of such excess, or, as Bailly expresses it, is the exaggeration of that assemblage of organic acts which complete a nycthemeron, and which takes place in the following manner:—1st, morning congestion of the stomach and intestines; 2d, augmentation of the different nervous influences which it produces throughout the system, and which according to the particular disposition of the individual gives rise to one set of nervous symptoms rather than another, or which excites that part of the nervous system which penetrates all our organs accompanied by blood-vessels when intermittent fever takes place; 3d, cessation of this congestion by the horizontal position.

It would be unjust to deny the ingenuity of all this, which has received much more illustration from its author than we can transfer to our pages; but it must be remarked that it proceeds on the supposition that the cause of ague exists in the digestive canal, which in the present state of our knowledge of the subject can be considered as little more than a postulate, and whilst it provides an explanation for quotidian intermittent, leaves tertians and quartans unexplained, which are considerable lacunæ in the hypothesis. Other speculations have been offered to the world, one, for instance, by M. Roche, who says that intermitting fevers arise from intermitting causes. These prevail in spring and autumn, when there is a great difference between the temperature of day and night, and when in a few hours there are sudden alternations from great heat to comparative cold; the malaria, too, which is generated is intermitting in its operation, for that which is produced in the middle of the day is so diffused by the rising of the heated air which is impregnated with it, that it does not act, but when concentrated in the condensed and chill air near the surface of the earth, cooled by radiation during night, it is in a state fit to produce its effect on the system. Did each paroxysm require for its production the application of cold or malaria, and were it in the instantaneous effect of such application, there might be some foundation for this hypothesis; but when it is considered, (even granting what is by no means proved, that malaria acts only at night,) that a considerable period generally elapses between the first exposure to the action of the poison and the appearance of the disease, that indeed there must be such an interval if the poison is to act intermittingly or by a succession of nightly applications, then it becomes manifest that to assume that the disease must imitate the preceding movements of its cause is the most extraordinary *non sequitur* that ever entered into the mind of man. This becomes still more manifest when we reflect that one single exposure to malaria will produce, days or weeks after, an attack of ague which shall last for weeks or months; as is often exemplified in the case of sailors sleeping one night on shore; and happened to a friend of the writer, from resting, when travelling, for a

few hours in a marshy situation where ague was prevailing.

Masked intermittents.—These may be succinctly described to be certain diseases familiar in a continued form to medical men and our nosologies, recurring at intervals in paroxysms of greater or less duration, when thus periodical apparently owing their origin to the influence of malaria, and remediable by the means employed to cure intermittent fever.

It were no easy matter to give a detailed account of all the diseases which have been observed under this intermitting form; to name those which have been remarked by authors to put on this character will be sufficient to make the profession aware that, whilst malaria is in operation, they must not expect all the diseases which are the result of it to assume the regular form of ague, but that such curious and anomalous disorders as those of which we are about to furnish them with little more than a list, will fall under their observation, and will require for their cure a treatment different from that of their continued type.

These diseases are either inflammatory or nervous. Of the first class there have been mentioned examples of pneumonia;* pleuritis, tertian;† carditis;‡ otitis;§ peritonitis (fell under the writer's own observation); ophthalmia, frequent; coryza, frequent; tertian swelling of the head;|| quotidian and tertian urticaria;¶ quotidian scarlatina; livid spots, probably of purpura, quotidian;** tertian erysipelas;†† rheumatism, quotidian, tertian, and quartan;‡‡ gout, first quotidian, then double quartan; epistaxis, quotidian; intermittent odontalgia and cephalalgia, very frequent; quotidian inflammation of leech-bites;§§ encephalitis and meningitis, quotidian, tertian, and quartan;||| gastro-enteritis;¶¶ diarrhoea, tertian*** and quotidian, frequent (from the writer's observation): and dysentery has not unfrequently been found complicating the paroxysms of an intermittent; but it may be questioned whether it have itself been met with as an independent intermitting disease meriting the name of a masked intermittent. Other intermitting inflammations are mentioned by authors, but on close scrutiny it will be found that many of these diseases have been permanent, and that the observers have not duly discriminated between a diminution of intensity and total intermittence.

Of the nervous affections the following are the most remarkable: asthma, frequent, but many cases which have occurred in the practice of the writer lead him to suspect that the periodical exacerbation of permanent bronchitis has been occasionally confounded with intermitting dyspnoea; periodical hysteria and epilepsy, frequent; intermitting deafness, type tertian;* tertian convulsions and blindness;† quotidian dumbness;‡ periodical sneezing, three paroxysms occurring every evening, and each paroxysm comprising three hundred sneezes;§ tertian eructation, at the rate of three hundred eructations per hour;|| periodical flow of leucorrhœa, with lypothymia, convulsions, and mutism; intermitting palsy is mentioned by many, and an excellent example of intermitting hemiplegia of the left side is related in Dr. Elliotson's lectures published in the Medical Gazette. It was generally tertian or quartan, but once recurred at the interval of sixteen days.

But neuralgia is by far the most common form of masked intermittent, exceeding in frequency of occurrence, so far as the writer has had opportunities of observation, all the other forms of this disease collectively; and it may be questioned whether many cases, supposed to have been examples of the periodical recurrence of inflammatory disease, were any thing but a painful affection of the nerves of the part. The anterior tibial, occipital, and sciatic nerves have been observed to be the seats of quotidian, tertian, double tertian, or quartan neuralgia.¶ Many cases, commonly entitled spasmodic asthma, have been supposed by some to depend on the same disease situated in the pneumo-gastric nerves, and instances of intense periodical pain in the region of the heart, extending thence to the middle of the left biceps, with small and fluttering pulse, deadly paleness, and inability of making the slightest movement, which the writer strongly suspected to be the same affection seated in the cardiac nerves, and which were remedied by quinine and anodynes, have fallen under his observation. But the branches of the fifth pair of nerves are certainly more frequently than any other the parts affected by periodical neuralgia, and we shall describe the disease, when so situated, as the representative of all its forms. It prevails much in spring, particularly during the prevalence of strong easterly winds, affects most the quotidian or double tertian type, and the invasion of the paroxysm often takes place at ten or eleven in the morning, but occasionally at night, and sometimes as early as three in the morning. Its commencement is marked by a very slight chill, amounting perhaps to little more than some coldness of the hands and feet. Slight pain

then begins to be felt either above the orbit only, or both in the forehead, over the cheek, and along the gums of the affected side. This speedily becomes agonizing, and is often attended with injection of the conjunctiva of the same side, lachrymation, abundant discharge from the corresponding nostril, and flushing of the cheek. This goes on for a period varying from four to six hours or longer, then subsides with slight moisture of the skin, and finally disappears totally, with the exception of a little soreness of the part which had been the seat of pain. During the paroxysm there is heat of surface, and the pulse becomes rapid and is increased in force. Throughout the disease the urine is high-coloured, and deposits a brick-dust sediment; and the tongue is furred, till the state of the digestive organs is corrected by proper remedies.

Treatment.—The principles of treatment so fully explained under the head of simple intermittent, apply to masked ague, the antiperiodic remedies possessing the same power here as in the more usual forms of the disease, provided the intermission be perfect and the paroxysms recur periodically. In treating the neuralgic forms, it will generally be advisable first to correct the state of the digestive canal by mercurial alteratives and purgatives, and then to endeavour to prevent the recurrence of the paroxysms by the sulphate of quinine or arsenical solution. It may be remarked that we shall often find the latter remedy succeed where the former has failed, and inversely. Carbonate of iron, not accounted a remedy of common ague, has succeeded, when given in doses of a drachm every three hours, where both had been tried without effect, and a case fell under the writer's observation which yielded to powdered bark, after it had resisted the other means mentioned. It is often advisable, especially in the case of females, who are more frequently the subjects of this disease than the other sex, to add some preparation of opium or hyoscyamus to the antiperiodics; and in all cases it is proper to give a full opiate at the commencement of the paroxysm. Covering the parts which are the seat of pain with a plaster of the extract of belladonna frequently diminishes its intensity.

Any notice of those purely sympathetic intermitting paroxysms which are occasionally met with in affections of the urinary organs and in certain chronic visceral diseases, not in their origin at all associated with ague, would be misplaced in this article.

(Joseph Brown.)

FEVER, REMITTENT.—This term is employed to designate a fever of which the symptoms undergo at intervals during its course a marked abatement or diminution, which is called a remission. Such a fever may be considered as holding a middle rank, as to external character, between intermittent and continued fevers; but with respect to its nature, the localities in which it chiefly prevails, and the cause whence it principally if not solely arises, it

bears a closer affinity to the former than the latter. It may be regarded more properly as forming the mean degree in the scale of periodic or marsh fevers, of which intermittent and yellow fever constitute the extreme points. A more intense operation of the febrile cause than is required for the production of intermittent fever engenders remittent, and the more violent the latter the more remote is its character from that of intermittent; or, in other words, the less perceptible the remissions. That a more powerful action of the morbid cause is demanded for the production of remittent fever, is indicated by the circumstance that when periodic fevers are prevailing in certain countries, the permanent residents are often observed to have the disease in the form of ague only, and the mortality among them is small; but strangers unhabituated to the climate and its diseases suffer from remittents, with a proportionally greater loss of life. In more sickly seasons remittents will be the prevailing form among both classes of persons, but strangers are more violently affected, and the mortality among them is greater. Its affinity to intermittent is shown, too, by the tendency which it has to pass into that form, and, inversely, by the proclivity of ague to assume the remitting type. (See INTERMITTENT FEVER.)

Remittent is the endemic fever of warm climates, especially of those of which the soil is marshy; but it is to be met with in the more temperate regions of the earth, and is not unfrequently observed in our own country, especially in seasons of unusual heat, and in those parts of it where under ordinary temperatures agues are prevalent.

In all countries which it invades, this disease is more generally observed in autumn than in other seasons of the year; but it is not unfrequent in summer, and is occasionally seen in spring. The writer has witnessed it in this country in winter, but, from the feeling of indisposition which had long preceded the manifest attack of fever, he had no doubt that the cause was applied the preceding autumn.

Symptoms.—The disease sometimes occurs suddenly, but more frequently it is preceded by unpleasant sensations at the stomach, listlessness, headach, and watchfulness of some days' duration. Its actual invasion is indicated by a feeling of coldness of the extremities and back, and sometimes by general coldness and actual shivering. This sense of coldness speedily alternates with flushes of heat; the mouth at the same time is clammy or dry; there are considerable thirst, nausea, and occasionally vomiting; pains in the head, back, and limbs, with a hurried respiration; and frequent, small, and sometimes irregular pulse. To these symptoms succeeds a stage of excitement, accompanied by a high degree of heat perceptible to the hand of the attendant as well as to the feelings of the patient; dry skin, violent and throbbing pain in the head, flushed countenance, a rapid, full, and forcible pulse, and sometimes delirium. The tongue is at the same time white and furred; there is generally

some tenderness of the epigastrium, with nausea, and occasionally vomiting either of mere watery secretion or of bilious matter. The urine is high-coloured, the bowels are generally torpid, and the thirst is considerable.

In about twelve or fourteen hours, though sometimes not till nearly double this period has elapsed, there is a manifest remission of these symptoms; a moderate perspiration breaks out, the nausea and vomiting (if it has existed) cease, the pulse becomes softer and less frequent, the thirst abates, the heat of the surface is diminished, and the mental state becomes rational and tranquil; but there is by no means a total cessation of fever, and after a comparative calm of two or three hours' duration, there is a renewal of the more intense symptoms of excitement, occasionally preceded by chill or even rigor, but occasionally without such a precursor. After this the disease proceeds in its course, with remissions and exacerbations very variable in their degree and period of recurrence, till about the seventh day, but in other cases till the fourteenth, when all the symptoms cease with a general and copious perspiration, and frequently an abundant eruption of herpes labialis.

The preceding sketch is drawn from examples of the mildest form of the disease, occurring in a warm climate, and in individuals of a vigorous constitution. It will be readily understood that the varieties arising from the different degrees of intensity in the usual cause, from circumstances which modify the action of this cause, and from peculiarities of individual constitution, must be so numerous, that the attempt to represent them all to the reader would be an insupportable tax on his attention and memory. We shall therefore present a picture taken from cases of the most aggravated form of the disease, leaving many intermediate degrees and varieties to be discerned clinically by the practitioner by the aid of some general observations on them, and the circumstances to which they owe their peculiarity.

This form, like the preceding, commences with a sense of coldness and sometimes with shivering, but in general the feeling of cold is rather long-continued than great in degree. It is followed by excruciating pain of the head, with a sense of tightness as if the skull, on a level with the upper part of the orbits, was firmly girt with a cord. The countenance becomes flushed, of a purple hue, agitated, and expressive of pain and anguish; the eyes are vascular and watery; the tongue is white, clammy and moist, or rough, dry, and brown; and pains are felt in the back and lower extremities, those in the latter resembling the sensations which attend the cramps of cholera. Nausea is an invariable symptom, and there is occasionally vomiting of viscid secretion; the intellect is confused, with short bursts at intervals of outrageous delirium, and the pulse is frequent, small, and contracted, and occasionally irregular. The skin is either dry, or, if moist, the moisture is of a nature which indicates rather intensity of suffering than energy of circulation; the heat of the surface on the

first application of the hand is not found to be great; but on longer or firmer pressure the fingers perceive a tingling sensation, the *calor mordax* of writers; the bowels are either obstinately costive, or there are frequent, scanty, and loose stools; and the urinary secretion is either very much diminished or totally suspended.

After this state has endured about twelve hours, a remission takes place, the patient remaining very ill and feverish, yet with less suffering than before; but this tranquillity is of short duration, for in less than six hours in some cases, in twelve or fourteen in others, a slight chill is felt, and there is a renewal of the symptoms described in the last paragraph, with the additional circumstances of a sense of pain in the epigastrium, much increased on pressure; irregular distribution of heat, the *præcordia* being excessively warm, whilst some other parts of the surface are cold; incessant restlessness and jactitation; hurried or laborious breathing, and such insensibility of the skin that blisters sear but do not vesicate. In fatal cases these symptoms endure in varying degrees of intensity, but with very imperfect remissions, from five to seven days. The approach of death is denoted by hiccup, distressing vomiting, hemorrhage from the intestinal canal, sinking of the pulse, muttering delirium, and coldness and lividity of the surface.

Recovery may be expected if the pulse becomes more full and expansive, the heat more equalized over the surface, the pain of the head and epigastrium less distressing, and if the countenance, though still flushed, loses the purple hue which it previously possessed. A favourable inference may be drawn, too, from the remissions becoming more distinct, the conjunctivæ being less vascular, the bowels more obedient to the action of purgatives, the restoration of a more abundant urinary secretion, and the appearance of bile in the matters vomited. These changes, which indicate relief from oppression, and restoration of natural secretion, with the continuance of open and safe vascular excitement, are generally the result of medical treatment. The mean duration of this form of fever, in cases of recovery, is about fourteen days.

The character of remittent fever is modified by the season in which it prevails. In spring, for example, it is more frequently associated with affection of the organs seated in the thoracic cavity, than with prominent cerebral or abdominal complication. In summer, during which season, in the climates which are most frequently visited by it, determinations of blood to the head are frequent from insolation, and even from the high degree of heat independent of exposure to the direct rays of the sun, the brain is the organ which presents the most marked symptoms of affection. The operation of this cause is frequently aided, especially among British troops in warm climates, by the abuse of fermented liquors and ardent spirits. In autumn an affection of the abdominal viscera constitutes the most prominent local affection, generally associated, it is true, with marks

of disorder in the brain and its membranes; but it is prior to such disorder in time, and exceeds it in degree.

This disease, which is so rapid in its march under the ardent heat of tropical climates, when it appears in more temperate regions, for instance in our own country, runs a longer course than any fever, hectic excepted, with which we are acquainted; and its exacerbations and remissions are more distinct than in warmer climates, but exceedingly irregular in the period of their recurrence. The former are not unfrequently ushered in by rigors nearly as severe as those of ague, or by a very well-marked chill; and occasionally so complete a remission occurs as to deceive the attendant by inducing him to suppose the patient convalescent: it has appeared to the writer that this very considerable abatement in the intensity of the disease is most apt to take place at one of the septenary periods from its commencement, especially about the fourteenth or twenty-first day. The whole course of the fever is frequently of forty or fifty days' and occasionally of nine or ten weeks' duration. Its great length is often attributed to relapses, but in the majority of such instances which have fallen under the writer's observation, he has had reason to think that remission had been mistaken for convalescence. This fever is not uncommon in this country and other temperate climates in autumns of unusual warmth; and occasionally, too, it is observed in the beginning of winter, but the cause, it will be found, had been applied during the preceding season.

A striking peculiarity frequently to be observed in the mental state of patients labouring under remittent fever has received little attention from authors, having been noticed only by the late Dr. Jackson,* and in a work published some time ago by the writer of this article.† Instead of the ordinary form of febrile delirium, in which the mind appears occupied with a crowd of unconnected ideas, and quite abstracted from surrounding objects, it in this case retains all its acuteness of perception and vigour of reasoning; but there is one erroneous impression so firmly fixed in it that no argument can shake it, and it is frequently of so gloomy a cast as to impel its victim almost irresistibly to suicide. To accomplish this object, (and in too many cases which fell under the writer's observation it was accomplished,)* the patient will often display all the cunning of a monomaniac. In many cases the impression was that of being causelessly abandoned to the scorn of the world; and in others, of a disgraceful imputation having been fixed upon the character, of the falsehood of which no proof could be obtained. Dr. Jackson relates a case in which the patient, in the exacerbation of a remittent, believed he was to be hanged for stealing coals; during the remission the illusion

ceased; but it recurred with the succeeding paroxysm, and he then declared himself resigned to his fate, and thankful for the respite of the preceding day, that of the remission. It is scarcely necessary to remark that the crime for which he supposed he was to suffer was as imaginary as the punishment which awaited it. During this mental derangement,—an appropriate term, for it has the characters of derangement, not those of delirium,—the patient, so far from there being any general obscuration of the intellect, often displays a self-possession and an acuteness of the mind above the ordinary level of his character. This peculiar state is not often observed in cases of the disease which are physically bad ones, nor is it confined to the advanced stage, when the mental as well as the bodily powers might be supposed to be enfeebled; but it exists from an early period, and is perfectly consistent with a considerable degree of general strength. It is more frequently observed among persons of the upper walks of life and of education, than among those of inferior station and attainments: the officers of the army in Spain, for instance, were more frequently the subjects of it than the soldiers, and it often fell to the writer's lot to see medical officers suffering under it.

No decided peculiarity has been detected in the symptoms during life, or the structural changes discoverable after death, to explain the striking discrepancy from the ordinary form of delirium which occurs in these cases. In all of them there has been evident derangement of the digestive canal, and its subsidiary viscera; and this derangement, in general so apt to produce mental despondency, is acting on a sensorium enfeebled and irritated by fever; but the same circumstances exist in other cases, in which there is either no aberration of mind, or in which, if it exists, it assumes the ordinary febrile form. We are therefore compelled to suppose that some peculiarity of individual constitution co-operates with the disease in engendering this unusual form of delirium; but there is considerable difficulty in discovering in what this individual peculiarity consists. A tendency to actual insanity will not explain it, for delirium has borne this appearance in individuals who have at no other period of their lives manifested any indications of that malady, and the mental illusions always cease on the subsidence of the fever. As it is more frequently observed in intellectual and educated persons than in those of a different class, perhaps mere sensitiveness will explain it; but the subject is involved in much obscurity.

Another form of mental affection not uncommon in this fever, is an indelible impression on the mind of the patient of the necessary fatality of the disease, though there may be nothing in its physical symptoms to excite the apprehension of the attendant. We know not whether this can be considered as a mental illusion or not, for in every case which has fallen under our observation the patient's prediction has been fulfilled, and we feel in doubt whether the mental impression was instrumental in the accomplish-

* Sketch of Febrile Diseases, by Robert Jackson, M. D. p. 123, et seq. London, 1817.

† Medical Essays by Joseph Brown, M. D. p. 48, et seq. London, 1828.

ment, or whether it did not itself proceed from some deadly feeling of the patient which language could not express, and of which the cause did not display itself by manifest signs. Dissection has thrown no light on this point.

Certain disorders are found to follow remittent fever. Of these, diarrhoea and dysentery are most frequently observed, and it may often be remarked that one or other of these disorders, especially the former, prevails simultaneously with it, and an attack of either of them appears to be equivalent to one of fever, those who suffer from the one escaping the other. Occasionally, too, an attack of bowel-complaint, accompanied with constitutional disorder, precedes the invasion of remittent, and passes so insensibly into it, that the attendant is at a loss to say at what precise time the fever commenced. Dropsy is a frequent sequel of this fever, especially of the cases complicated or followed by diarrhoea. In cases in which the head has been much affected by the disease, the mind, during convalescence, betrays a degree of feebleness almost approaching to idiocy, from which recovery is very slow.

Appearances on dissection.—The changes of structure discovered in fatal cases of this disease resemble so much, or rather are so identical with those observed in complicated and malignant intermittent, of which a full account is given in the preceding article, that a brief narration here, and a reference to that article, will furnish the reader with ample information on the subject.

In the head are observed, vascularity of the membranes of the brain, and effusion of serum or gelatinous fluid between them; fluid in the ventricles in greater quantity than is ordinarily observed, and oozing of blood on cutting the hemispheres transversely; but it must be remarked, that occasionally death, preceded by delirium or coma, takes place, and yet no morbid appearance of the brain or its membranes can be discovered; and we may go further, and state that cases have terminated fatally, and, on examination by acute and experienced observers, no structural change of any organ has been detected; though it must be acknowledged that such cases are so rare as to constitute the exception, not the rule.

In the chest, adhesions and serous effusion are occasionally discovered between the pleurae and in the pericardium; the bronchial lining is frequently unusually vascular, and the parenchyma of the lungs is congested or inflamed. These changes are most discernible in vernal remittents. On examining the abdomen there are found inflammation and sometimes ulceration of the lining of the digestive canal, with occasionally an effusion of blood between the mucous and subjacent coat. The liver and spleen are often enlarged, and unusually soft; and the urinary bladder is occasionally contracted in size, and has its mucous lining studded with clots of blood.

The question of the nature of periodic fever having been discussed at some length in the article on intermittent, to examine how far

these pathological states are strictly essential to the disease, or are to be regarded as mere concomitants or effects, would inevitably lead to a repetition of the arguments employed in that article, which we are desirous of avoiding. British writers on remittent fever have generally confined themselves to the relation of facts, and in their works it has generally been implied, if not positively stated, that this fever like others is a condition distinct from inflammation, but very generally associated with it, and that this association should receive full attention in the treatment. The French writers assume a more decided tone, and a numerous class of them, proceeding from the postulate that every fever commonly considered essential or primary is but a symptom of a local inflammation, regard periodic fevers as mere indications of intermitting or remitting phlegmasie. M. Rayer's doctrine is different from this. According to his views, intermittent fever is a cerebro-spinal neurosis, and remittent fever he degrades from the rank of a disease capable of nosological classification to that of "various complications of intermittent fever with other disorders."*

Treatment.—This, as in the case of most fevers, must vary so much according to the various circumstances of the disease, that it is impossible to lay down rules with respect to the employment of any remedy which shall not admit numerous exceptions.

General bloodletting, in attacks of the more ardent forms of remittent, may be employed freely at the commencement of the disease, and its repetition may be speedily required in such cases, if the force of the circulation is not diminished by the first bleeding, and especially if there are indications of cerebral affection; and even in the more sunk and depressed forms, one bleeding at the commencement relieves the system, and, aided by the warm-bath and other remedies, conduces materially to the safety of the patient. Good effects are occasionally obtained in the latter description of cases, by drawing the blood whilst the patient is in the warm-bath; but we should be more sparing in quantity than in attacks of a more ardent disease. In the more protracted disease of temperate climates, it will rarely be advisable to perform more than one general bleeding, and even this in delicate subjects may be frequently dispensed with.

Free local bleeding, by cupping or leeches, from the vicinity of organs affected with inflammation, is always safe at the commencement of remittent, and may be often performed with advantage at a late stage.

Purgatives, so administered as to unload the bowels without needlessly irritating them, are valuable remedies. Pills of calomel, with a proportion of extract of colocynth, powdered rhubarb or jalap, followed by a solution of neutral salts, answer the purpose exceedingly well.

In the more intense and excited variety of

* Dictionnaire de Médecine.

the disease, cold affusion may be employed during the exacerbation with great benefit; in milder cases, cold sponging at intervals during the same period will accomplish our object with less shock to the feelings of the patient.

Cooling, acidulated drinks, and draughts with liquor ammoniæ acetatis, or the ordinary saline draughts, tend to allay thirst, and, on the whole, to diminish the degree of excitement. There is so great a tendency to vomiting in this disease, and if excited it is so difficult to subdue it, that antimonials are not suitable remedies.

The local affections which manifest themselves during the course of the disorder require attention. If there be much pain of the head, with or without delirium, besides bleeding by leeches from the temples, the scalp should be shaved and kept incessantly cool by sponging with cold water, or the constant application of wet cloths. Vomiting, which is a very distressing symptom, is most effectually relieved by the application of leeches and hot fomentations to the epigastrium, followed by a blister and the internal employment of some preparation of opium, for which the ordinary effervescing draught furnishes a convenient vehicle. Should diarrhoea exist, leeches, and subsequently a blister to the umbilical region, unloading the bowels with castor oil, and afterwards the employment of hydrargyrum cum cretâ with Dover's powder, will be found to be its most suitable remedies.

Independently of its effect in relieving vomiting or diarrhoea, opium is a valuable remedy in the advanced stage of the disease, to allay irritation and procure sleep. Mercury is of use as a purgative, and as a means of correcting the morbid secretions and condition of the intestinal canal, and the organs associated with it; but the attempt to supersede the febrile action in remittent by bringing on that of mercury we have never seen successful. It is true that on the subsidence of the fever pyalism takes place, and is often exceedingly injurious to the patient; but there is never reason to think it instrumental in producing convalescence.

We are recommended by some writers to attempt to cut short the disease by the administration of bark, arsenic, or other antiperiodic remedies as in intermittent; but the remission must be so perfect as to amount to an actual apyrexia, and the disease must, therefore, become identified with intermittent, before such a plan can be attempted with propriety; for we have almost uniformly observed that the employment of any antiperiodic in actual remittent not only failed in its object, but has invested the disease with a more continued and dangerous character.

The diet at the commencement of the disease should consist of the lightest and most cooling diluents, such as tea, tamarind-water, lemonade, &c.; but in the advanced stage more nutritious matters, sago, arrow-root, panada, chicken-broth, and even a little wine may be allowed. In some of the more sunk and

oppressed forms, it may be advisable to give wine or other stimulants cautiously at an early period.

As soon as the patient's state will admit of his being removed, it is advisable that he should, if possible, quit the district in which the disease has been generated.

(Joseph Brown.)

FEVER, INFANTILE REMITTENT.—

By infantile remittent is now commonly understood a species of fever to which children, from one year old up to ten or twelve, are very subject, characterized by one or more daily exacerbations and remissions, by pain of the belly and sometimes also of the head, and by an unnatural state of the alvine discharges. This, in the language of the older writers, from its supposed but imaginary cause, was usually denominated a worm fever.

In the last century, indeed, many epidemics, even of adults, were thought to receive their peculiar type or character from the presence of worms, and were distinguished from other fevers by the name of *febres verminosa*. The existence of worms in fevers is now universally considered by all but the vulgar, amongst whom the exploded doctrines of antiquity so often and so obstinately linger, as a mere accidental complication, which may present itself in epidemics of the most different characters, and which exercises little influence either over their progress or their appropriate methods of cure.

During the greater part of the eighteenth century, however, the opposite opinion maintained its ground. Thus Baglivi says, let the diseases of children be what they may, we ought always to suspect worms; and some later writers, amongst whom Van den Bosch rendered himself conspicuous, attributed almost all diseases to the generation of worms in the intestines. Sauvages gives a list of upwards of twenty disorders which he supposed occasionally to have a similar source. Hoffmann endeavours, but very unsatisfactorily, to account for the frequent non-appearance of worms where he had expected to meet with them, in the following passage: "*Pleurumque tamen vermes non excernuntur si febris juncta, quia æstu febrili dissolvuntur in putridum magma.*" The morbid intestinal secretions were thus evidently mistaken by him for the remains of dead and corrupted worms, and it exemplifies a fact of which unfortunately instances are not wanting even in our own day, namely, that preconceived and theoretical notions may go a great way to counteract and pervert even the testimony of our senses.

The importance of worms continued long to be overrated even after Pringle and Sarcione had remarked that their presence in fevers scarcely required any peculiar modification in the treatment of these disorders; and after Bianchini in Italy, and De Haën in Germany, had pointed out how exaggerated was the influence attributed to them by some other writers. Yet even De Haën himself did not

rise altogether above the prejudices of his age on this matter, as he admitted the occasional existence of verminose epidemics, pleurisies, &c.

To British writers much of the credit of exposing and refuting this antiquated opinion is due. St. Clair, of Edinburgh, about one hundred years ago, proved that worms were not always discovered in the so-called worm fever, and pointed out the uncertain nature of most of the symptoms supposed to indicate their existence. Dr. Hunter declared that he had searched for them in vain in those who were said to have died of such disorders; and Musgrave proved that those affections were attributable less to the presence of these parasitic animals than to *saburræ* in the *primæ viæ*. Dr. Clark of Newcastle, on his work on fever, remarks on the impropriety of the term worm fever, and dwells upon the fact which he had ascertained by experience, that anthelmintics will rarely if ever cure it. In the year 1782, Dr. Butler's work on the Infantile Remittent Fever appeared, and it has continued ever since to be the chief authority on this subject. In this treatise he has approximated still more nearly to the truth than any of his predecessors, attributing the symptoms of the above named fever almost exclusively to a weak state of the digestive organs, to morbid accumulations in the *primæ viæ*, and to that peculiar irritability of habit and proneness to fever which distinguish the period of infancy. There is not, he asserts, the least ground for regarding worms in the treatment of the infantile remittent. He thinks, indeed, that they are deserving of little attention in the treatment of any of the diseases of children, except so far as is absolutely necessary for the satisfaction of friends; for though their existence may be a proof of disease, they are neither a cause nor a necessary symptom of such disease. He supports the singular opinion that they are nature's resource for consuming the superabundant morbid humours, and for stimulating the intestines by their movements, and thus assisting the peristaltic motion to carry off the remains of the offending load. This startling proposition, as to the positive utility of worms, which is sometimes attributed to Dr. Butler and sometimes to Rush, does not appear to have originated with either of them, as we find the following passage in Røderer and Wagler's valuable treatise "*De Morbo Mucoso*," of which the first edition appeared in 1762.—"*Infantibus cæterum plethoricis pauciores hospites intestinales verâ emolumento sunt, modestâ consumptione superfluum nutrimentum corpori noxium subtrahunt.*"

Dr. Rush, from the frequency with which worms occur both in the young of the human species and of the lower animals without appearing to produce any disease, inclines to the opinion that they must serve some useful and necessary purpose in the animal economy, such as consuming the superfluous aliment which all young animals are disposed to take,

and even suggests the probability of children sometimes being disordered for the want of them, asserting that it is in the grossest and most vigorous children that they are most frequently found. Worms are often discharged in small-pox and measles from children who never had any symptom of them before, and are frequently discharged in swarms during fevers of all kinds. In the existence of such a disease as the idiopathic worm fever Rush has no belief, coinciding in opinion with the Indians of America, who ascribe the occasional discharge of worms to the fever, and not the fever to the worms. He admits, however, that they may sometimes give rise to anomalous symptoms in the course of a fever, and justify the blending of anthelmintics with the ordinary treatment. The symptoms said to indicate their existence are most deceptive, and none more so than that which is usually so much depended on, the picking of the nose. The actual discharging of worms from the bowels is, perhaps, the only symptom that is truly pathognomonic of their presence. Gardien, on the other hand, ridicules the idea of worms answering any beneficial purpose in the intestinal canal, and asserts that they occasionally give rise to a species of hectic fever. In support of this he states that he had himself met with one example of this, and refers to Morton and Truka for others. He supposes them to be injurious, both by absorbing the chyle, and by the irritation they produce.

Sydenham is thought to have alluded cursorily to the infantile remittent, describing it as a kind of hectic, which holds children a long time, during which they languish with little heat, a loss of appetite, and a wasting of the whole body; and from this description Sauvages has established his species *hectica infantilis*, which is not, however, very well characterized, and might apply to the symptomatic fever accompanying mesenteric and other scrofulous diseases, as well, or perhaps better, than to the one in question, with which it has, notwithstanding, been considered as synonymous by most subsequent writers. An equal degree of doubt attaches to the *febris lenta infantum* of Hoffmann, usually given as another synonym of the disease. The probability indeed is, that several very dissimilar affections were crowded together under these titles, at a period when diagnosis was so much more imperfect than at present.

The infantile remittent, according to Dr. Butler, is distinguished by drowsy exacerbations, wakeful remissions, pain of the head and belly, total loss of appetite, little thirst, and slimy stools. He admits three varieties of the disease, viz. the acute, the slow, and the low infantile remittent.

The acute infantile remittent may begin suddenly, but is more commonly preceded for several days by symptoms of indisposition: the child looks unwell, and his colour is changed; he frequently picks his nose and lips, and has an offensive breath, short dry

cough, anorexia and flatulence, pain in the head and belly, with occasional enlargement of the latter. He starts, grates his teeth, and moans in his sleep; the urine appears milky soon after it is passed, and quickly deposits a whitish sediment. The belly is in extremes, either costive or loose. Fever soon supervenes, and is ushered in by a cold fit. The child is hot and restless at night, and diurnal exacerbations soon succeed. Of these there are often three in the twenty-four hours, one in the forenoon, one in the afternoon, and a third in the night, which is the longest and the most intense. When the fever is very severe, the remissions become very short and almost imperceptible. During the exacerbations all the symptoms become aggravated; the child is drowsy and sleeps, but not soundly, for he starts, moans, talks incoherently, and even screams in his sleep; there is a troublesome flatulence, more frequent cough, and accelerated respiration. Nausea and vomiting occasionally occur. The pulse varies from 140 to 160. In the remissions, all the symptoms abate; the child is wakeful and attentive to things around him, occasionally playful and disposed to leave his bed. If he chance to sleep, he now rests composedly, and the pulse is reduced to 120 or 130 in the minute. The skin is usually dry, both in the exacerbations and in the remissions; and if any sweats occur, they are partial, being limited to the head, breast, or palms of the hand. The abdomen and palms are always warmer than the rest of the body. There is complete loss of appetite, and hardly any thirst, so that the patient in some cases can scarcely be got to take either food or drink, and often rejects them by vomiting as soon as swallowed. The urine is of a transparent orange colour, and the stools are always unnatural, either as to their colour, consistence, or smell; thus they are either paler or darker than in a state of health, more offensive, consisting often almost entirely of slime, and occasionally frothing and fermenting like barm. Worms are in some cases thrown off by vomiting or stool, and sometimes crawl spontaneously out of the body either by the mouth or anus. As the fever declines, the exacerbations become milder and shorter, the appetite returns, long and refreshing sleep and a general moisture of the skin take place, the pulse falls, and the urine deposits a copious sediment, leaving the supernatant fluid of a straw colour; this sediment gradually diminishes, and the stools assume a healthy appearance. The pulse, however, occasionally continues quick long after all the other symptoms have disappeared, and till the patient has nearly regained his flesh and strength. The ordinary duration of the complaint is from one to three weeks or longer.

The slow variety of infantile remittent comes on with the same symptoms, but more gradually and imperceptibly than the acute, the flesh and strength slowly declining, the appetite being unequal, the belly often enlarged, and the breath offensive. There is but one

well marked exacerbation, which, taking place in the evening, lasts till morning, and is succeeded by a profuse sweat. Throughout the day the skin is dry and harsh, and hectic flushings are frequent. The pulse seldom exceeds 140 in the exacerbations, and is about 100 in the remissions. The patient is weak, indolent, listless, and disinclined to move, as any attempt at walking makes the limbs ache. Yet he is rarely so ill as to be confined to bed. The day as well as the night is passed mostly in dozing, and in his sleep he often starts and moans, and picks his nose and fingers till they become sore and scabby. The tongue is white and moist; there is no appetite, and little thirst; the urine is of a deep orange colour; that passed in the morning deposits a sediment—that during the day contains only a cloud. The stools are of the same unnatural character as in the acuter form. When the fever is about to decline, the nocturnal exacerbations and succeeding sweats abate; the flushings become less frequent, whilst all the other morbid symptoms gradually disappear, and the patient recovers his flesh, strength, colour, and cheerfulness. This variety may last for two or three months or more.

The low infantile remittent fever begins suddenly, and for the first week perfectly resembles the acute, save that the head is more affected, and delirium sometimes occurs. After this the low state succeeds, the child becoming quiet, indifferent to surrounding objects, and indisposed to answer questions. He rarely asks for any thing, but takes his food or drink when it is offered to him; the trunk and lower extremities generally remain fixed in one posture, but the arms and hands are almost always in motion when he is awake: sometimes he flings them about, and at other times picks not only his nose and lips, but even his tongue, eyes, and other parts of his face till they become sore. At the height of the disease the difficulty of replying to questions, arising from debility, terminates in a temporary loss of speech and voice, and the jaws are occasionally locked together. He slumbers much during the exacerbations, and in the remissions performs with his hand the gesticulations above described. When the low stage sets in, the eyes are reddish, dull, and inattentive; the countenance is expressive of distress, and the tongue, teeth, and lips are covered with a blackish fur. The patient is particularly uneasy before stools, or the escape of flatulence. The urine and stools, which are of unnatural appearance, are involuntary, yet he is quite sensible. The pulse, which is about 100 in the remissions, rises to 120 in the exacerbations. When the disease takes a favourable turn, the exacerbations become shorter, the child is less drowsy, the eyes are clearer and more observant, the countenance is placid, and the tongue cleaner, the pulse is calmer, and the appetite returns. The voice is regained, and, though weak at first, soon becomes stronger and is frequently exercised, as he cries whenever he is disturbed or wants any thing, or

if he feels himself unable to reply to questions, or to put out his tongue when desired. The strength, flesh, and colour are gradually recovered, and he yawns, sneezes, or coughs, which he was previously unable to do. The urine, which is of a straw colour, is still for a considerable time passed involuntarily. The crying and fretfulness long continue. The stools at length become natural, and there is no complaint made but of weakness. The pulse occasionally continues accelerated till the recovery is complete. The duration of this fever is from a month to six weeks, or even longer.

Perhaps the preceding account might be simplified with advantage in a practical point of view, and a nearer approach to the truth made, by considering the infantile remittent in the first place as a disease of indeterminate duration; by this the first and second subdivisions would be got rid of; and in the second place, as liable to be considerably modified by the habit and health of the individual, and the epidemic constitution of the season, which would enable us to discard the third variety.

According to Dr. Pemberton, who has given a simpler description of this disorder, the fever is merely symptomatic of derangement in the intestines. The affection comes on very gradually, and first manifests itself by irregularity in the bowels, which more frequently are costive, though sometimes they are too much relaxed. In the course of the day there are several slight accessions of fever, which are marked by drowsiness, the child in the intervals appearing perfectly well, though always peevish. The appetite is variable, and the pulse ranges from 100 to 130. This state of things lasts for eight or ten days, when all at once a more violent paroxysm preceded by rigour and vomiting takes place, the pulse rises in frequency, the drowsiness is increased, and the cheeks are flushed; but there is not the least pain complained of in any part, except now and then slight pains shooting through the abdomen. Incessant picking of the skin of the nose, lips, and angles of the eyes, is a symptom which is almost invariably present. The function of digestion seems to be almost totally at a stand, for if any food be taken it is brought up a considerable time after unaltered. "The intestines also seem to be in a manner paralysed; they exert no action on the food, for it passes off like a mass of putrid animal and vegetable matter which had been sometime subjected to heat and moisture, without its having the smallest resemblance either in appearance or smell to those faces where the powers of digestion have been exerted." The appetite is quite lost, and delirium occasionally occurs for two or three days together, but does not indicate that the case will be peculiarly severe or protracted.

There is a symptom which we have met with in this disease, which has been omitted in most of the descriptions of it, viz. a stiffness in the neck, and intolerance of pressure

in the upper part of the spine: with this a general increase of the sensibility of the whole surface of the body seems sometimes to co-exist, so that the child can scarcely bear to be touched in any part. The first of these symptoms has not, however, escaped Heberden. "In the fevers of children," says this accurate observer, "the face is sometimes drawn to one shoulder. I have often seen this, but never knew it continue long after the fever was cured." He alludes to it in another part of his work under the name of "the wry neck of children." Underwood has also noticed it. A similar stiffness about the nape of the neck occasionally occurs in cases of dyspepsia in adults.

The infantile remittent fever, according to Dr. Butter, may be either sporadic or epidemic, and in the latter case it appeared to him to be occasionally contagious. Dr. Sims gives the following description of an epidemic infantile remittent, which occurred simultaneously with the prevalence of a low nervous fever amongst adults. "It was called," says he, "by some a worm fever, though I believe worms were seldom the cause; yet, as that lay apparently in the stomach and intestines, the error did not materially effect the practice." The leading symptoms were heat, thirst, quick pulse, vomiting, coma, and sometimes slight convulsions, an universal soreness to the touch, troublesome cough, and extreme peevishness. The fever was constantly of the remittent kind, the cheeks often appearing highly-flushed, at other times very pale; it lasted for several days, but seldom beyond a week, and the fatality, though greater than in the fever existing at the same time among adults, was not very considerable. Many of those who were seized by it had been subject for a length of time to those symptoms which are thought to point out the existence of worms in the primæ viæ; such as picking the nose, grinding the teeth, and starting out of the sleep, swelling of the belly, white urine, short dry cough, &c. yet worms scarcely ever appeared.

From what we have seen of this affection, as well as from a careful consideration of the best descriptions which have been given of it, we are disposed to consider it merely as a variety of gastric fever, modified by the irritable constitution of infancy, and closely allied to, if not identical with the *febris pituitosa* of Frank. Feverish affections in all feeble and nervous subjects, as well as in infants, manifest a tendency to nightly exacerbations. Richter conceived that every fever which presents remissions partakes more or less of the gastric character; and Selle recognized no other kind of remittent fevers except the gastric and the hectic.

In France this affection is, like most other fevers, considered to be and treated as a species of gastro-enteritis. That a depraved state of the secretion of the mucous membrane exists is evident, but that this necessarily depends in all cases on inflammation has not been satisfactorily made out; and we believe that medi-

cines which slightly increase and modify the secretions of this surface will generally be found to conduct the disease to a favourable termination more speedily than the sole employment of directly antiphlogistic measures.

The irritation which exists about the nostrils and angles of the mouth, and the scabby eruptions which frequently appear in the latter of these situations, together with the state of the tongue, the total loss of appetite, the faint sickly smell of the breath, the morbid condition of the alvine secretions and of the urine, the swelling of the belly, the good effects of purgatives, and the fact that the gradual subsidence of the fever keeps pace with the improvement in the stools,—all taken conjointly seem to point in a manner which cannot be mistaken to the chylipoietic viscera as the original seat of the disease.

The premonitory symptoms, especially the obstinacy and irregularity of the bowels, fetid breath and gradual failure of the appetite, together with the causes of the disease, which seem to consist chiefly in the use of improper food and neglect of the bowels, (circumstances which, like the fever itself, are of much more frequent occurrence amongst the children of the poor than of the rich,) all tend to confirm the above view of the nature of this affection.

The prognosis, under proper treatment and exact compliance with directions on the part of the attendants, is mostly favourable. A return of appetite, an improvement in the character of the evacuations, and the remissions becoming lengthened, are signs of approaching health. If, on the other hand, the exacerbations increase in frequency, and the fever becomes almost incessant, and the abdomen swollen, the case is not without danger. In a fatal case of this kind recorded by Pemberton, the intestines on dissection were found enormously distended, and the mesenteric glands slightly enlarged. No inflammation, however, was detected either in the bowels, peritoneum, or any of the viscera, nor was there any effusion into the abdominal cavity. This inflation of the intestines and occasional enlargement of the mesenteric glands is also mentioned by Hoffmann. The infantile remittent sometimes passes into hydrocephalus, especially when it is neglected or mismanaged. The possibility of such a termination should never be forgotten, else the moment for active treatment will be lost irretrievably. Dr. Cheyne believes that such a transition would be much less frequent if it were more the practice to bleed children in those febrile attacks which commence with sickness, vomiting, and fullness of the hypochondria. Besides, cathartic medicines would then be found to act more readily, and the crisis would occur on an earlier day.

The diagnosis of infantile remittent from hydrocephalus often presents great difficulty. Sims believed that the distinction in children under five or six years of age was often impracticable until within a day or two of the fatal period, when the dilatation of the pupils, and insensibility of the eyes to light, point out the

latter disease too strongly to be mistaken. Pemberton, however, thinks that hydrocephalus may almost always be recognised by the screaming in the sleep, tossing of the hands over the head, and the continual effort to thrust the head backwards; by the intolerance of light, strabismus, interruption of the intellectual faculties, and by food being taken without discrimination or reluctance. In infantile remittent, on the contrary, there is seldom screaming or intolerance of light, there is no strabismus, the intellectual faculties can be roused, the appetite is so totally destroyed that the child can scarcely be persuaded to take either food or medicine. The discharges from the bowels are very unnatural, often black and smelling like putrid meat, sometimes curdled, with shreds of coagulable lymph floating in a dark greenish fluid. In very young children the irritation may cause convulsions, and during the fit it is totally impossible to determine whether the head or the intestines be their source. If, however, after the fit is over the faculties be completely restored, this, taken conjointly with the preceding symptoms of the case, will enable us to ascribe them pretty confidently to disorder of the intestines. Moreover, the convulsions in the latter case occur early in the disease, and occasionally usher in the fever.

According to Gölis, who has been at much pains to discriminate these affections, the infantile remittent, or mucous worm fever as he calls it, may be distinguished from hydrocephalus by having no distinct stages, the pulse being accelerated throughout, and never falling below the natural standard, and by the length of time to which the disease usually runs on, viz. from three to six weeks; by attacking phlegmatic, overfed, and large-bellied children; by its usually well-marked remissions; by the face being pale and swollen, the expression stupid, and the manner sluggish; by the dullness and indistinctness of the pains in the abdomen and head, which are indeed scarcely at all complained of; whilst in hydrocephalus the pain in the forehead is very acute, and alternates with that in the stomach or bowels, and is accompanied with a feeling of tension in the nape of the neck, and occasionally with pains in the limbs. In the worm fever the child sleeps soundly and is awakened with difficulty; it perspires freely after each exacerbation; it maintains its posture in bed, and does not toss about as in hydrocephalus: a strong light does not pain the eyes, nor is there blindness at any stage: the hearing is slow, particularly towards the end of the fever, whilst in hydrocephalus it is peculiarly sharp; the nostrils are moist, and the smell acute, and an intolerable itching is felt in the nose, all of which is otherwise in the affection of the head. In the infantile remittent vomiting is a rare and accidental occurrence, and the respiration is accelerated throughout the whole course of the disease; the bowels are comparatively easily acted on by medicine, and there is little wasting of the body or shrinking of the belly, but on the contrary much flatulent distention. If

convulsions occur, they are not followed by permanent paralysis. The miliary eruption, so frequently associated with gastric diseases, may appear, but it is quite unlike the peculiar exanthematous affection described by some of the German writers as occasionally occurring in the last stage of hydrocephalus.

The means recommended by Dr. Butter for allaying the febrile irritation consist in keeping the patient quiet in bed in a chamber of moderate temperature, and from which the light is in a great measure excluded. All solid food and stimulating drinks are to be withheld, and diluting and slightly nourishing fluids freely supplied, as weak broths, gruel, and barley-water. The bowels should be kept gently open, so that one stool may be procured daily in the low fever, two in the slow, and three or four in the acute variety. For this purpose he was in the habit of giving the preference to the neutral salts, and especially to the sal polychrest, on account of its promoting urine as well as stools, and allaying, as he thought, the febrile irritation by its operation on the nervous system even before it had produced any sensible evacuations. For a child of five years old he usually ordered one drachm of the above salt dissolved in four ounces of water, and sweetened with two drachms of sugar. Of this mixture two spoonfuls were to be taken from time to time, so as to finish it in twenty-four hours. When the body was sufficiently open, he sometimes substituted the nitrate of potass; or when diarrhoea existed, five grains of the extract of conium dissolved in the same quantity of water as the preceding mixture, and to be taken in the same manner. The quantity of extract of conium given daily was in the proportion of one grain for every year of the child's age, and a sufficient quantity of sugar was added to render it palatable. He thought the hemlock had much influence both in relieving the fever and carrying off the looseness. In the slow fever, where the neutral salts failed, he sometimes employed the extract of conium with good effect, at the same time keeping the bowels open with sal polychrest, or with a moderate dose of rhubarb nightly. In this variety he also recommends three or four drops of elixir of vitriol every fourth hour, and the use of weak wine whey by turns with broth and gruel. In some cases bark appeared useful, though he rarely found it necessary to have recourse to it. If the child be very noisy and restless, the abdomen should be repeatedly fomented, by which the patient will often be speedily tranquillized and sleep induced. This measure is especially necessary when the abdomen is tense and swollen.

Such is the plan of treatment recommended by Dr. Butter; but in an affection where there is such strong evidence of deranged and deficient action, not only of the bowels themselves, but also of the stomach, liver, and other viscera concerned in digestion, stronger medicines, which may have a greater power of restoring or modifying the function of secretion in these organs, seem called for. Under this impression

we usually commence with a few doses of calomel, rhubarb, and jalap, in addition to which, if the bowels be very obstinate, a mixture of infusion of senna with salts may be necessary. The occasional interposition of calomel and antimonial powder at night has sometimes seemed to have considerable influence both in improving the stools and in controlling the febrile symptoms. A similar practice is strongly recommended by Dr. Cheyne in his work on hydrocephalus. "Antimonials," says this able practitioner, "in combination with cathartics, and more especially calomel, have appeared to me very useful in those cases of infantile remittent fever in which the sensorial functions are much oppressed, as also in the commencement of febrile attacks of a less definite nature, which are liable to degenerate into hydrocephalus. In such cases I prescribe a pill of calomel and antimonial powder three times a day, interposing between every two pills a moderate dose of the common purgative mixture."

Though advocates for the purgative system in this disorder, we are convinced that it may be, and often is, pushed quite too far. To clear out the bowels, and gradually to modify the alvine secretion, should be our sole object. The danger of inordinate evacuations in this disease was well known to Sydenham, who confined his treatment to an infusion of rhubarb in beer, made so weak as to act rather as a mild aperient and stomachic than as a purgative. By over-purging, the tone of the intestines may be totally destroyed and tympanitis induced. If the case runs on for several weeks, enemata and alternate doses of rhubarb and hydrargyrum cum cretâ, or the latter alone, if the bowels be sufficiently free, may be had recourse to. In very obstinate cases, repeated doses of calomel combined with opium and antimony have been found useful by Dr. Hamilton. With a view of restoring the tone of the intestines and stomach, Dr. Pemberton was in the habit of giving thrice a day a light and aromatic infusion of cascarrilla throughout the whole disorder. In an advanced period of the disease fractional doses of the sulphate of quinine may tend to accelerate convalescence. Dr. Clarke, to whose work we have already alluded, is, however, an advocate for an earlier employment of bark, to which, after the exhibition of an emetic, and one or two doses of an active purgative, he had immediate recourse. "By this means," says he, "the nervous symptoms which so frequently accompany fevers in the delicate habits of children, are for the most part happily obviated." Any little experience we have had in this mode of practice has by no means tended to confirm its propriety.

Manningham, in his treatise on the Febricula in adults, an affection which has many points of analogy with the remittent fever of infancy, appears to have been very averse to the use of bark, as well as of bloodletting and strong purgatives, confining himself to a mild emetic at the commencement, and to occasional doses of rhubarb, and gentle diaphoretics

throughout, along with effervescing draughts during the exacerbations. Stoll, in speaking of the febris pituitosa, which frequently runs on for several weeks, asserts that a very cautious and temporising method of treatment is the safest and most successful. We cite these authorities rather to shew the necessity of great circumspection in the treatment of this disease, than to justify a timid or inert line of practice.

When recovery has at length taken place, a return to the usual diet and way of life should be very gradual, and attention to the regulation of the bowels long persisted in. Preparations of iron, together with country air, regular exercise, and light nutritious food, are the most effectual means of re-establishing the constitution in its original vigour.

(W. B. Joy.)

FEVER, HECTIC. Our word hectic, derived from the Greek *ἡκτική*, habitual, is often used substantively, like the Greek feminine, to denote an habitual or very protracted fever; but more generally it is employed in conjunction with the word fever to designate the same disease.

This fever is attended by the following symptoms. The general appearance of the surface is pale, excepting the cheeks, on which there is often a delicate and circumscribed bloom. There is emaciation, which is progressive, and sometimes very rapidly so, although the appetite is good and the digestive functions appear to be well performed. The pulse is generally hard, and in point of frequency always above the healthy standard of the individual affected, but particularly so at two periods of the day, noon and evening, when there is an exacerbation of all the febrile symptoms, most conspicuous at the latter of these periods; and these exacerbations are preceded by a chill, generally slight, though sometimes considerable. The respirations are rapid and short, readily accelerated by any exertion, and attended frequently with a cough, even where an affection of the thoracic organs is not the source of the disease. The skin is warm, especially in the palms of the hands and on the face, and at the commencement of the fever generally dry; but before it has lasted long, there is a disposition to perspire on any exertion, and a gentle perspiration may generally be observed after the noon-day exacerbation, and one very profuse towards morning, which may be considered as the resolution of that of the evening. The urine is various, being sometimes pale and without deposit, and at others high-coloured, and letting fall a lateritious sediment. The bowels at the commencement of the disease are often costive, and occasionally remain so to the close; but more commonly a colliquative diarrhœa occurs in the advanced stage. The tongue is generally clean; as the disease advances it frequently becomes dry and glazed, and ultimately its surface is covered with aphthæ; there is considerable thirst; a sense of dryness in the throat and fauces; and in the

latter stage of the disorder these parts manifest the same aphthous appearance as the tongue. The eyes are generally bright and expressive, with the conjunctivæ of a pearly whiteness; the nails become incurvated; the adipose and muscular substance are rapidly absorbed, so that the eyes are sunk in the orbits, the temples excavated, and the whole frame is much attenuated, excepting the inferior extremities, which are often œdematous; the sleep is disturbed and unrefreshing; and there is a continual feeling of lassitude and debility; but, with all this failing of the physical powers, the mind remains cheerful and unclouded, and seems to gather hope from the causes of despair.

With respect to mere external character, hectic bears a greater affinity to periodic than to continued fevers, and of the former resembles most the remittent; though cases are occasionally observed in which the severity of the rigor preceding the exacerbation, and the almost complete apyrexia consequent on the sweating stage, assimilate it considerably to intermittent. As to its intrinsic nature it may be considered as the general irritation produced by the sympathy of the constitution with a local disease, "of which it is conscious, and which it cannot relieve itself of and cannot cure."* A severe and enduring local affection is required to produce hectic; but at the same time it is to be remarked that peculiarity of individual constitution is an important element in its production. An amount of local suffering with which a robust constitution might fail to sympathize, or with which it might not sympathize in the form of hectic, may, in a person of more delicacy and mobility, produce what Mr. Hunter has very happily termed this "slow mode of dissolution." The amount of local affection requisite to produce this disease varies, too, according to the nature and functions of the parts in which such affection is seated. The system will much more readily sympathize with an abscess or other disease of a vital organ, such as the lungs, heart, liver, stomach, intestines, mesenteric glands, or kidneys, than with a similar disorder existing in the muscular or cellular tissue near the surface of the body. Diseases of parts of which the powers of reparation are feeble, and which consequently, when diseased, keep up a protracted irritation in the system, often give rise to hectic. Hence we frequently observe it as a consequence of diseases of bone, ligaments, and tendons, and of abscesses connected with diseases of these tissues, such as psoas abscesses and those produced by diseased joints. If the nature of the local affection is such as the powers of the constitution have little or no controul over; if, for instance, it is scrofulous, cancerous, rachitic, and particularly if it is tubercular, hectic very generally arises; and likewise, on the same principle, it is not unfrequently produced by a

* Hunter on the Blood, vol. ii. p. 377. London, 1812.

long-continued mechanical irritation, as that of a calculus in the kidneys or bladder, or of a foreign body in the trachea, (of which a case is related by Borelli,) and on the removal of the irritating cause it occasionally ceases.

Mr. Hunter was of opinion that hectic might be an original disease of the constitution independent of any local cause; and Dr. Willan, Dr. Perceval of Dublin,* Trnka, and some others have expressed the same sentiment; but it is by no means a general one. Mr. Hunter guards his opinion by a qualification, for he states that the constitution may fall into this mode of action without any local cause "*that we know of*;" and on examining the evidence on the subject, we are led to conclude that this qualification explains the existence of a sentiment in this author and others so little in accordance with that of the profession generally, and that the imperfection of diagnosis alone has led to the supposition that this may be an idiopathic disease. We are told, for instance, that hectic may exist without pulmonary affection for three months, and then break out in the lungs.† From the extreme difficulty of detecting the presence of tubercles in their unsoftened state, even with the improved methods of diagnosis now employed, is it not reasonable to conclude that these bodies had existed in the lungs undetected, and produced the fever; since we find this affection, which of all is most frequently attended with hectic, ultimately displaying itself by manifest signs? The writer saw some years ago a case of apparently idiopathic hectic which proved fatal; an examination of the body showed the existence of small abscesses in the muscular substance of the heart; and we believe that in other instances, what is supposed to be primary hectic is equally the sign of an undiscovered local irritation or lesion. A fever in all respects resembling hectic supervenes on profuse hemorrhages; but this will not be found on consideration to form an exception to the general rule. The system is left by hemorrhage in a state favourable to the production of this form of disease on the application of any irritating cause, and the nutriment given to recruit the strength of the patient, acting on the enfeebled alimentary canal, becomes such a cause, for hectic will ever be found most apt to occur in such cases where a stimulating regimen is employed.

Treatment.—On this branch of the subject we have little that is satisfactory to communicate. If the local cause is of a nature to admit of correction, or if irremediable, so situated that it can be removed, the accomplishment of one or the other should be attempted; but in the majority of instances neither is practicable. The constitutional treatment is principally restricted to regulating the bowels by gentle laxatives when the patient is costive, or by opiates and astringents when diarrhœa exists.

The diet should be light and nutritious; and a pure and moderately warm air should be selected for the patient when circumstances render it attainable. Tepid, or even cold ablutio, or sponging during the height of the febrile exacerbation, is refreshing, and tends to diminish the colliquative perspirations. Tonics have been recommended, and sulphuric acid is as eligible as any medicine of this class; but they do not merit much confidence. Besides the use of opiates to check diarrhœa, they may be employed to allay irritation and procure sleep.

(Joseph Brown.)

FEVER, PUERPERAL. This term was first employed by Dr. Strother, in the year 1716, to designate the most fatal inflammatory disease to which child-bed women are liable. The name is now generally employed by medical writers, and it is considered to be synonymous with the terms puerperal peritonitis, child-bed fever, puerperal fever, or the epidemic disease of lying-in women.

The records of medicine afford indubitable evidence of the fact, that puerperal or child-bed women have, from the most remote periods of antiquity, been liable to attacks of this destructive affection. In the works, however, of the earlier authors its history is short and imperfect; and it is probable that the disease did not attract the particular attention of physicians before the middle of the seventeenth century, when it occurred at Paris as a malignant epidemic in the lying-in wards of the Hôtel Dieu. Since that period it has often been observed in the principal cities and lying-in hospitals of Europe, both in a sporadic and epidemic form.

The most vague and contradictory opinions have hitherto prevailed respecting the nature and treatment of this disease. Inflammation of the peritoneum, omentum, or some of the abdominal viscera, has been considered as the cause of all the phenomena; and for the treatment, copious bloodletting and cathartics have been recommended. Other writers, who refer all the local and constitutional symptoms to a specific fever, peculiar to women in the puerperal state, deprecate the employment of venesection, and urge the necessity of employing the most powerful stimulants and cordials. The morbid sensibility of the hypogastrium, usually observed at the commencement of the attack, and the changes of structure from inflammation often discovered after death, both in the uterine and other organs, they have considered as the consequences of this idiopathic fever, in like manner as inflammation of the brain, lungs, or intestines, often supervenes in the progress of typhus.

Those who have most attentively perused the works of Hulme, Leake, Denman, Walsh, Gordon, Joseph and John Clarke, Hamilton, Hey, Armstrong, Douglas, Mackintosh, and Campbell, must have been convinced that the pathology of puerperal fever required a more complete investigation than had been made by

* Note on Good's Study of Medicine, first edit. vol. ii. p. 167.

† Mason Good, loc. cit.

any one of these distinguished authors. To reconcile their discordant statements with respect to the nature and treatment of the affection, it appeared requisite that it should be examined not only in hospitals, but also in private practice, for several successive years, throughout all the different seasons. In this manner only did it seem possible to ascertain whether they had described diseases essentially distinct, or merely varieties of the same affection, modified by some powerful but unknown causes.

From the 1st of January, 1827, to the 1st of June, 1832, one hundred and sixty-two cases of well-marked puerperal fever came under our immediate observation in private practice, and in the British Lying-in Hospital, and other institutions in the western districts of London. We watched the symptoms and progress of these cases with the closest attention, observed the effects of the different remedies employed, and, where death took place, we carefully examined the alterations of structure in the uterine and other organs.

Of fifty-six cases which proved fatal, the bodies of forty-four were examined, and in all there was found some morbid change, the effect of inflammation, either in the peritoneal coat of the uterus, or uterine appendages, in the muscular tissue, in the veins, or in the absorbents of the uterus, which accounted in a most satisfactory manner for all the constitutional disturbance which had been observed during life. The peritoneum and uterine appendages were found inflamed in thirty-two cases; in twenty-four cases there was uterine phlebitis; in ten there was inflammation and softening of the muscular tissue of the uterus, and in four the absorbents were filled with pus. These observations are subversive of the general opinion now prevalent in Europe and America, that there is a specific, essential, or idiopathic fever, which attacks puerperal women, and which may arise independent of any local affection in the uterine organs, and even prove fatal without leaving any perceptible change in the organization of any of their different textures. As the constitutional symptoms thus appear invariably to derive their origin from a local cause, it would be more philosophical, and more consistent with the correct principles of nosological arrangement, to banish entirely from medical nomenclature the terms *puerperal* and *child-bed fever*, and to substitute in their place that of *uterine inflammation, or inflammation of the uterus and its appendages in puerperal women*. The terms *puerperal peritonitis* and *peritoneal fever*, employed by some English and foreign physicians, are not less objectionable than *puerperal fever*, for in many of the fatal cases there is no proof whatever of the existence of any affection of the peritoneum.

All writers agree that in puerperal fever there is exquisite sensibility of the abdomen with pyrexia, and that these are the only invariable and characteristic symptoms of the disease. After the inflammatory symptoms of the uterine

organs subside, those of collapse follow, as in the last stages of inflammation of the brain, lungs, liver, intestines, and other abdominal viscera: then the belly becomes distended and tympanitic; and after death extensive alterations of structure remain in the uterus and its appendages; while the other important external and internal organs present no morbid appearance. Besides there is nothing which can be discovered in the condition of a puerperal woman to render her more liable to attacks of typhous fever than any other individuals; and lying-in women, as we had an opportunity of observing in the epidemic typhus of Edinburgh in the years 1816 and 1817, and during the last five years in this metropolis, are rarely affected with common typhus. It is to the uterus, which is left in a condition after delivery to which no other organ of the body is ever similarly placed, and which renders it peculiarly liable to attacks of inflammation, that we are to look for an explanation of all the phenomena of puerperal fever.

Until a recent period, the pathological anatomy of the uterine organs in puerperal women had not received that due attention which its importance demanded. In the histories of the different epidemic fevers which have prevailed amongst lying-in women since the middle of the seventeenth century, the symptoms and the morbid appearances, though imperfectly described, nevertheless strongly confirm the accuracy of the conclusion, that the whole phenomena, local and general, of these fevers, are to be referred to inflammation of the uterine organs; and that the symptoms vary according as the superficial or the deeper-seated structures of the uterus are affected.

It is stated by Peu, that in 1664 a prodigious number of puerperal women perished in the Hôtel Dieu, and that the cause of this mortality was attributed by M. Vesou, physician to the hospital, to the circumstance of the lying-in wards being situated immediately over those set apart for the reception of individuals who had been wounded. The women were attacked with hemorrhages, and on opening their bodies they were found to be full of abscesses.*

This brief and imperfect account of the disease when first observed as an epidemic, is interesting from this circumstance, that no further notice is taken of it by the French writers during the succeeding hundred and twenty-two years, for the whole of which period the lying-in wards of the Hôtel Dieu remained contiguous to the wards of the sick and wounded. It is not distinctly stated by Vesou whether it was in the uterus, or in the viscera of the thorax, head, or abdomen, that abscesses were observed on dissection; but it will hereafter appear that the presence of abscesses in any part of the body of a woman who has recently been delivered is one of the strongest proofs which can be obtained of the previous

* Peu, *Pratique des Accouchemens*, p. 268.

existence of inflammation in the deeper-seated textures of the uterine organs.

The winter of 1746 at Paris was most destructive to puerperal women, and they died between the fifth and the seventeenth day after their confinement. The epidemic attacked the indigent, but much less frequently those delivered at their own habitations than in the Hôtel Dieu. Of twenty women in child-bed affected with the disease in February of that year in the Hôtel Dieu, scarcely one recovered.*

M. Malouin has given the following history of the symptoms and progress of this epidemic. "The disease usually commenced with a diarrhoea, the uterus became dry, hard, and painful; it was swollen, and the lochia had not their ordinary course; then the women experienced pain in the bowels, particularly in the situation of the broad ligaments; the abdomen was tense; and to all these symptoms were sometimes joined pain of the head, and sometimes cough. On the third and fourth day after delivery the mammae became flaccid. On opening the bodies curdled milk was found on the surface of the intestines, a milky serous fluid in the hypogastrium, a similar fluid was found in the thorax of certain women, and when the lungs were divided they discharged a milky or putrid lymph. The stomach, the intestines, the uterus, when carefully examined, appeared to have been inflamed. According to the report of the physicians, there escaped clots on opening the vessels of this organ."

"This terrible disease," says M. Tenon, "has shewn itself at different epochs, and its returns have been more frequent than ever; it reappeared every winter from 1774; it commenced usually about the middle of November, and continued till the end of January. It is met with also at the other seasons of the year, even during spring, for it has come to prevail more and more, and to be as it were naturalized.†

"Those who were attacked in the years 1774 and 1775 died between the fourth and seventh days after delivery, and seven out of every twelve women who were delivered were seized with the disease. Two distinct forms of it were successively observed, one a simple form, which was cured by ipecacuan; the other a complicated form, for which there was no remedy; so that there perished in 1816, one of every seven of those who were attacked with puerperal fever, and death took place from the sixth to the eighth day after delivery, and often much earlier.

"The first symptoms manifest themselves twenty-four, thirty-six, or forty-eight hours after delivery, and sometimes, but rarely, in the space of twelve hours: The symptoms of the simple puerperal fever are developed in the following order; rigor, slight pain in the region

of the kidneys, intestinal colic, which in two hours affects the whole hypogastrium, and gradually becomes more acute. Pulse concentrated, fever moderate, lochia not suppressed; mammae flaccid, tongue dry in the middle, covered with a yellow mucus on the edges; hiccup, and vomiting of green-coloured matters. There was sometimes combined with these constant and characteristic symptoms of the disease which took place in the years 1774 and 1775, a diarrhoea of a bilious glairy matter, a considerable swelling of the hypogastrium, thirst, and remarkable retention of urine.

"In the complicated puerperal fever, the pyrexia is stronger, with exacerbations; the tongue is black and dry, the belly is tense, distended and tympanitic, and slightly painful. In some women the lochia have been either wholly suppressed or only diminished, others have experienced attacks of ophthalmia; in some the respiration was difficult; in general the blood shewed the buffy coat.

"On opening the abdomen, the stomach, the intestines, particularly the small intestines, were inflamed, adhering to one another, distended, filled with air and a yellow fluid matter. The uterus was contracted to its ordinary dimensions, and was seldom found inflamed. I had occasion to dissect two; in one the uterus contained a coagulum of blood; an infiltration of a milky appearance or whey-like fluid existed in certain women in the cellular membrane which surrounds the kidneys. Sometimes, also, a thick, white, cheesy matter was met with. When the lungs were gorged with blood, or inflamed or emphysematous, an effusion of serum was found in each side of the chest. We did not observe the hemorrhages which occurred in the epidemic of 1664, and the uterus was not found dry, hard, and tumefied as in that of 1746. In the epidemic of 1774, the lochia flowed, but they did not flow in 1746."

From 1782 to the present time, the same fatal disorder has appeared at different times in the Maternité at Paris, and in many of the continental lying-in hospitals, and the same morbid appearances have been observed on dissection.

The bodies of fifty-six women were examined who had died of puerperal fever in the general hospital at Vienna, in the autumn of 1819, and in all of these, with the exception of two, where delivery had taken place a considerable time previous to death, effusions of sero-purulent fluid were found in the abdominal cavity, and traces of inflammation in one or more of the abdominal viscera. The ovaria and fallopian tubes were always more or less swollen, red, and tender, and the body of the uterus was, in consequence of inflammation, flabby, tender, and easily broken down with the finger. It is also stated in the report of this epidemic, that the accession of fever is always preceded by marked changes in the whole system, particularly in the uterus, clearly indicating an inflammatory state. The symptoms indeed were such, that the inflam-

* *Mémoires de l'Académie des Sciences pour l'année 1746.*

† *Mémoires sur les Hôpitaux de Paris*, p. 243.

mation combined with high fever could not be mistaken.*

Pinel, Bichat, Laroche, and Gardien found the peritoneum inflamed in so many fatal cases of puerperal fever, that they have considered this disease essentially to depend on inflammation of the peritoneum. A French author, who has subsequently observed the disease, and who entertains the same views of its nature, asserts that nothing can be more absurd, more chimerical, or more contrary to the spirit of analysis and observation, than the idea that there is a fever essential or peculiar to women recently delivered.

If we consult the works of the most celebrated writers in this country on puerperal fever, it will clearly appear that they all describe the disease as commencing with a sense of soreness or exquisite tenderness in the region of the uterus; and that where it proves fatal, the appearances on dissection are such as afford unequivocal proofs of inflammation of one or more of the pelvic and abdominal viscera.

Strother, Burton, Millar, and Wallace Johnson, state that the distinguishing marks of the disease are pain of the hypogastric region, abdomen, and loins, and that relief often follows venesection.

Drs. Hulme and Leake considered inflammation of the omentum to be the proximate cause of puerperal fever, and the latter suspected that the whole mass of circulating blood becomes contaminated by absorption of the fluids effused into the peritoneal sac. "Considering," observes Dr. Leake, "the suppuration of the omentum, and large quantity of purulent fluid in the abdomen after death, it is easy to see how a secondary fever, which was truly inflammatory at the beginning, may soon become putrid by absorption of that fluid, which, like old leaven, will taint the blood by exciting a putrid ferment in the whole mass, and change its whole qualities into that of its own morbid nature. Some of those who survived recovered very slowly, and were affected with wandering pains and paralytic numbness of the limbs, like that of chronic rheumatism. Some had critical abscesses in the muscular parts of the body, which were a long time in coming to suppuration, and, when broke, discharged a sanious ichor."†

Dr. William Hunter observes, that on examining the bodies of those who have died from puerperal fever, the viscera and every other part of the abdomen are found to be inflamed. There is a quantity of purulent matter in the cavity of the abdomen, and the intestines are all glued together.

Pain of the head and abdomen with fever were the symptoms which Dr. Lowder considered to be pathognomonic of the disease; and redness of the peritoneum, adhesion of the intestines, effusion of serum mingled with pus

and lymph, the most frequent morbid appearances.

The history of the symptoms and morbid changes of structure, by Drs. Joseph Clarke, Gordon, Campbell, Mackintosh, and other writers, is nearly the same; and Professor Hamilton, who believes that puerperal fever is a *fever sui generis*, nevertheless admits that the appearances on dissection are exactly similar to the descriptions generally given by those authors, and that acute pain of the abdomen is a primary and not a secondary symptom of the disease. Dr. Hamilton positively affirms that puerperal fever is a disease of a "putrid" nature, requiring for its treatment, wine, volatile alkali, bark, glysters, and animal jellies; and yet, in direct opposition to these theoretical views, and as if involuntarily led by the symptoms to a correct conclusion respecting the true character of the affection, he has laid down as the first indication of treatment to moderate local inflammation by purging and hot fomentations.

It is a singular circumstance that in none of the works to which we have now referred has the most remote allusion been made to inflammation of the veins, absorbents, or any of the other structures of the uterus, except the peritoneal covering, though several of them have accurately described the constitutional symptoms which characterise these morbid states.

In the epidemic fever which prevailed at Aberdeen between the years 1789 and 1792, Dr. Gordon examined the bodies of three patients who died of the disease, and in each the peritoneum and uterine appendages were inflamed. "The omentum," he observes, "does not appear to be more especially affected than the other productions of the peritoneum, which are all equally and indiscriminately affected. The dissections which I have made, prove that the puerperal fever is a disease which principally affects the peritoneum and its productions, and the ovary. The peritoneum was inflamed, and the omentum, mesentery, and peritoneal coat of the intestines were all promiscuously affected." Venesection and cathartics were found to be the most powerful remedies.*

Dr. J. Clarke admits that in most cases of the true puerperal fever there has been some degree of inflammation in the cavity of the abdomen, and that the uterus and ovary sometimes partake of the inflammation. In two cases which he met with, there was an appearance of pus in the veins of the uterus. The brain was always in a natural state. In one instance only was there an appearance of disease in the chest. The effusion of sero-purulent fluid into the sac of the peritoneum was so disproportioned, however, to the degree of inflammation, that he supposed it to have arisen from another cause. Pathologists now admit that these copious effusions into the peritoneal sac are invariably the result of acute inflammation, and not of any peculiar disposition

* Medical Annals of the Austrian States, 1822.

† Leake on Child-bed Fever, &c. vol. ii. pages 90-92.

* Treatise on the Epidemic Puerperal Fever, 1795.

of the vessels of the part, as Dr. Clarke had supposed.*

The works of Dr. Armstrong and Mr. Hey contain the histories of two epidemics, in which the leading symptoms were those which are present in cases of abdominal inflammation, and the employment of copious bloodletting, cathartics, and other antiphlogistic remedies, was attended with decided advantage. The actual condition of the uterine and other organs was not, however, ascertained by either of these writers, as they were not permitted to examine the bodies of any of those who were cut off with the disease.

The more recent works of Drs. Campbell and Mackintosh may also both be referred to, in confirmation of the truth of the pathological doctrines we shall endeavour to establish; and the statements of Dr. Gooch, if carefully examined, will be found to support rather than to weaken the force of our conclusions. As a substitute for the ordinary names, child-bed fever, puerperal fever, and peritonitis, he has employed the term peritoneal fever "to express the fact that an affection of the peritoneum is an essential accompaniment of the disease, without defining what that affection is, because it is not uniform." This term, peritoneal fever, is perhaps the least appropriate of all the terms that Dr. Gooch could have invented; for he admits that the disease may occur in its most exquisite form, and yet leave few or no traces in the peritoneum after death by which we might have been enabled to determine that this membrane had previously been the seat of the disease.

"The most remarkable circumstance," Dr. Gooch observes, "which the experience of the last few years has taught us about peritoneal fevers is, that they may occur in their most malignant and fatal form, and yet leave few or no vestiges in the peritoneum after death. The state of this membrane, indicated by pain and tenderness of the abdomen, with a rapid pulse, appears to be not one uniform state, but one which varies so much in different cases that a scale might be formed of its several varieties; this scale would begin with little more than a nervous affection, often removable by soothing remedies, and, when terminating fatally, leaving no morbid appearances discoverable after death. Next above this, a state in which this nervous affection is combined with some congestion, indicated, in the cases which recover, by the relief afforded by leeches, and in the cases which die, by slight redness in parts of the peritoneum, and a slight effusion of serum, sometimes colourless, sometimes stained with blood. Above this might be placed those cases in which there are in the peritoneum the effusions of inflammation without its redness, namely, a pale peritoneum and no adhesions, lymph like a thin layer of soft custard, and a copious effusion of serum rendered turbid by soft lymph. Lastly, the vestiges of acute in-

flammation of the peritoneum, viz. redness of this membrane, adhesion of its contiguous surfaces, a copious effusion of serum, and large masses of lymph."*

Dr. Gooch affirms that symptoms and dissections cannot settle the question respecting the pathology of puerperal fever. "The effects of remedies on a disease," he says, "if accurately observed, form the most important part of the history. They are like chemical tests, frequently detecting important differences in objects which previously appeared exactly similar. Symptoms and dissections can never do more than suggest probabilities about the nature of a disease and the effects of a remedy on it. A trial of the remedies themselves is the only conclusive proof."

We might appeal to the works of all the most eminent writers on puerperal fever since the middle of the seventeenth century to prove that this opinion is equally erroneous as it is dangerous; and it would be easy to shew, from the contradictory statements of the effects of the various modes of treatment adopted by physicians during the last fifty years, that we must have for ever remained ignorant of the true nature of the disease, if we had reasoned from the effects of remedies alone, without investigating symptoms and morbid changes of structure.

That a diffused pain of the abdomen with a rapid soft pulse not unfrequently occurs at particular seasons, without inflammation of the uterus or of any other part, or with a very slight degree of inflammation, in delicate nervous women after parturition, and that these symptoms are relieved by opiates and warm fomentations, without either general or local bloodletting, will readily be admitted by all who are conversant with the diseases of the puerperal state. That such cases are, however, if not essentially different in their nature, at least widely different in degree of severity from cases of sporadic or epidemic puerperal fever or uterine inflammation, is clearly demonstrated by the following observation made by Dr. Gooch himself: "There seemed to be nothing dangerous in this form of disease, provided the nature of it was not mistaken and improper remedies not used, yet it so strikingly resembled peritoneal inflammation that it was invariably taken for it by the practitioners who witnessed it, all of whom possessed at least that average quantity of sense and knowledge on which the public must extensively depend."

There can be little doubt that in numerous instances the irregular spasmodic contractions of the uterus constituting after-pains, and irritation of the intestines have been mistaken by superficial observers for puerperal fever, but such mistakes do not prove the identity of these affections. The results of the practice in the Westminster Lying-in Hospital in the years 1828 and 1829, referred to by Dr. Gooch, prove beyond contradiction that the cases described

* Essays on the Epidemic Disease of Lying-in Women, by J. Clarke, M.D.

* An account of some of the most important diseases peculiar to women, by Robert Gooch, M.D.

by him under the term peritoneal fever, were not genuine examples of low child-bed fever, as he has maintained; for of twenty-eight women who were attacked with the disease, and most of whom were treated as he had recommended, with Dover's powder and warm cataplasms, seven died, or one in four.

In investigating the morbid anatomy of this class of diseases, Dr. Gooch appears to have been satisfied with simply inspecting the peritoneal covering of the uterus; now we are strongly inclined to believe, from what we have ourselves observed, that if he had carefully examined the spermatic and hypogastric veins, the absorbents, the uterus and its appendages, with the sub-peritoneal tissues, he would frequently have found acute inflammation or some of its products. With the phenomena of inflammation of the deep-seated structures of the uterine organs he appears indeed to have been perfectly unacquainted, as they are not even alluded to in the course of his essay, and are generally confounded with the effects of loss of blood. The absence of increased vascularity of the peritoneum, and of lymph and serum in its sac, does not prove that the subjacent tissues are in a healthy state. That a nervous affection or congestion of the peritoneum should give rise to all the symptoms and consequences of fatal uterine inflammation, is not only highly improbable, but is wholly unsupported by facts. Had Dr. Gooch estimated more correctly the value of pathological anatomy in discovering the nature of disease, and placed less reliance on the uncertain operation of remedies, he could not possibly have fallen into so many important practical errors with respect to puerperal fever, and to some of the organic diseases of the uterine organs in the unimpregnated state.

The recent valuable researches of Andral, Luroth, Dance, Danyau, Tonellè, and Dupley, confirm in a remarkable manner the accuracy of the views we have now stated of the proximate cause of puerperal fever. In the epidemic of 1829 at Paris, numerous opportunities occurred of examining the morbid appearances in those who were cut off by the disease. In one hundred and thirty-two out of two hundred and twenty-two fatal cases, purulent fluid was found in the veins and absorbents of the uterus, and in one hundred and ninety-seven some important alteration of structure was observed in the uterine organs. In a few rare cases described by M. Tonellè under the term ataxic puerperal fever, the changes which had taken place in the uterine organs were comparatively slight, and consisted of an exudation at the neck of the uterus and some lymph effused into the cavities of the uterine veins. In these cases the symptoms were considerably different from those commonly observed in uterine inflammation, and were possibly referable to other causes.

The whole of the preceding statements seem to warrant the following general inference, which we ventured to draw from our own observations in October, 1829: "That inflammation of the uterus and its appendages must be considered as essentially the cause of all

the destructive febrile affections which follow parturition, and that the various forms they assume, inflammatory, congestive, and typhoid, will in a great measure be found to depend on whether the serous, the muscular, or the venous tissue of the organ has become affected."*

We shall now proceed succinctly to describe the various changes produced by inflammation in the uterine organs subsequent to parturition;—to point out the local and constitutional symptoms by which these morbid conditions are characterized during life, and by which they are distinguished from other affections to which they bear a resemblance;—to investigate the causes and nature of this disease;—and to describe the treatment adapted to the different varieties of uterine inflammation, and the most important means to be adopted for its prevention.

The following are the principal varieties of inflammation of the uterus in puerperal women which we have observed.

1. Inflammation of the peritoneal covering of the uterus and of the peritoneal sac.
2. Inflammation of the uterine appendages; ovaria, fallopian tubes, and broad ligaments.
3. Inflammation of the muscular and mucous tissues of the uterus.
4. Inflammation and suppuration of the absorbent vessels and veins of the uterine organs.

These varieties of uterine inflammation may take place quite independently of each other, though they are most frequently met with in combination. Peritonitis seldom occurs without some inflammation of the uterine appendages; but we have found both these textures severely affected while the muscular coat of the uterus and the veins were wholly exempt from disease. The venous and muscular tissues of the uterus are also liable to attacks of severe inflammation without any corresponding affection of their peritoneal covering, though it most frequently happens that inflammation, when excited, either in the veins or muscular coat of the uterus, involves also the peritoneum. In the organs of respiration similar varieties of inflammation are observed, and the pleura, pulmonary texture, and mucous membrane lining the air-passages, may all be separately or simultaneously involved in the same attack. A similar observation may be extended to the brain and its membranes, and to the whole of the digestive organs; and the symptoms which characterize the inflammation of the different tissues of which these organs are composed, have been more accurately determined than formerly by the recent discoveries of pathological observers.

Inflammation of the uterine organs, like inflammation of the lungs and other affections of a similar character which assume an epidemic form, takes place more frequently at one season than another, and at one period the peritoneum is the tissue most commonly affected, whilst at other seasons the deeper-seated tissues are almost invariably found in-

* Med. Chir. Transact. vol. xv. part ii. p. 405, 1829.

flamed. That there is no essential difference between these varieties of uterine inflammation is proved by the circumstance that in the course of a few days, in the same ward of the British Lying-in Hospital, and in patients who were placed in contiguous beds during the prevalence of the epidemic, when the disease appeared to be communicable from person to person, peritoneal inflammation, uterine phlebitis, and the other varieties above enumerated, all occurred in their most marked or characteristic form. In some patients the local and constitutional symptoms indicated the presence of acute inflammation of the serous covering of the uterus; and in those cases where active depletion was had recourse to at the commencement of the attack, most frequently a speedy recovery took place. In other examples, at the onset of the disease, there was comparatively little pain in the region of the uterus, the pulse was from the beginning rapid and feeble, and the symptoms were such as to contraindicate the use of bloodletting and cathartics. Such cases usually terminated fatally in defiance of local bleeding and the exhibition of mercury and opium, and other remedies; and on examination after death, either the veins, the muscular structure, or the appendages of the uterus were found to be the textures most frequently inflamed.

These facts prove that at different seasons, different textures of the uterine organs are liable each to be affected with inflammation in varying degrees of intensity, and they enable us in some measure to reconcile the discordant opinions already quoted, both with respect to the symptoms and the treatment of puerperal fever.

1. *Puerperal peritonitis.*

Morbid appearances.—The peritoneum when inflamed becomes vascular, red, and apparently thickened, and the abdominal viscera adhere to one another by an effusion of lymph, or there is an effusion of a turbid serous fluid mixed with shreds of albumen or pus, sometimes tinged with blood, in greater or smaller quantity, into the cavity of the peritoneum. The omentum is often of a deep red colour, highly vascular, and closely adherent to the intestines, and sometimes to the fundus of the uterus, by lymph. The intestinal canal is frequently found much distended with air, at other times the sac of the peritoneum.

Puerperal peritonitis commences in the peritoneal covering of the uterus, and extends from thence with greater or less rapidity, according to the severity of the attack, to the whole peritoneum. In some cases the inflammation is confined to the uterus, and it is generally most severe in this situation, or in the parts immediately surrounding that organ. Even when it has extended to the other viscera, and affected them most severely, the peritoneum of the uterus invariably exhibits signs of recent inflammation. The lymph is for the most part thrown out in thicker masses upon the uterus than in any other situation, and this viscus seems always to suffer in the greatest degree. In the cellular membrane under the

peritoneum, serum and pus are also not unfrequently found deposited.

Symptoms.—Great tenderness of the hypogastrium increased by pressure, with pyrexia, are the characteristic symptoms of the disease. In every instance which has fallen under our observation, we have found the uterine region more or less painful on pressure, and there has been febrile disturbance.

When the attack is violent, the patient generally lies upon the back, with the knees drawn up to the trunk of the body. The abdomen at first is soft and flaccid, and, except in the region of the uterus, is frequently not affected by pressure. Though an enlarged and painful state of the uterus is never altogether wanting, yet the pain often undergoes exacerbations similar to after-pains, and is frequently mistaken for these by careless observers; and the true character of the disease is overlooked until a great part of the peritoneal sac is absolutely inflamed. The whole abdomen then becomes swollen and tympanitic, and the pain either wholly subsides or becomes still more intense than at the commencement. Vomiting of black or dark green coloured fluids follows, the pulse grows extremely rapid and feeble, the tongue dry and brown, the lips and teeth are covered with sordes, and death follows at no very remote period.

The manner in which the disease commences varies considerably in different individuals. The invasion of pain is sometimes sudden, at other times the ordinary increased sensibility of the uterus which remains after natural labour or after-pains, passes insensibly into the acute pain, increased by pressure, which is the chief pathognomonic symptom of this affection. Most frequently the accession of the disease is marked by rigors, partial or general, sometimes so slight as almost to escape notice, at other times so violent as to produce severe shivering of the whole body. The cold stage, after a longer or shorter duration, passes away, and is succeeded by heat of skin, suffusion of the countenance, acceleration of the pulse and quick respiration, thirst, frequently nausea or vomiting, and intense pain across the forehead. Cough is also a common symptom of the disease. The rigors precede, accompany, or follow the increased sensibility of the uterus. In some of the most severe cases there has been no distinct rigor; but a quick pulse, hot skin, and hurried respiration have rapidly succeeded to the uterine pain. In most of the fatal cases the countenance has from the commencement been anxious and pallid, and the extremities cold.

There is no uniformity to be noticed in the appearance of the tongue in puerperal peritonitis. It is sometimes entirely covered with a thin, moist, white or cream-like film; at other times it is of a deep red or brown colour in the centre, with a thick yellow or white fur on the edges.

The lochia are often entirely suppressed; in other cases only diminished in quantity. The mammae usually become flaccid; yet in

some fatal cases the milk has been secreted until a short period before death.

This variety of uterine inflammation is frequently confounded with deranged states of the intestinal canal, the irregular spasmodic contractions of the uterus which constitute after-pains, hystericalgia, and simple suppression of the lochial discharge.

In cases of intestinal irritation, (or intestinal fever as it has been named by Professor Burns, and by Dr. Marshall Hall a serious morbid affection after delivery,) the pain is from the commencement of the attack diffused over the whole abdomen; it is a gripping rather than acute pain, does not commence in the region of the uterus, and is but little, if at all, aggravated by pressure. The abdomen is generally soft, puffy, and distended. The tongue is loaded; there is thirst and headach; neither the lochia nor the secretion of milk are suppressed. The febrile attack is usually preceded by evident signs of derangement of the bowels, such as flatulence, nausea, vomiting, constipation, or diarrhoea. Puerperal peritonitis is developed in a large proportion of cases before the end of the fourth day after delivery, whereas this affection of the bowels rarely appears until the end of the first week.

It is difficult in some cases to distinguish inflammation of the peritoneum from after-pains and hystericalgia. Where the pulse is accelerated, the remission of pain incomplete, the lochia scanty or suppressed, and the hypogastrium tender on pressure, we shall arrive at a correct diagnosis by considering the peritoneal coat of the uterus in a state of congestion and inflammation, and employing antiphlogistic treatment. There are few puerperal women, except those of a feeble and irritable constitution, or who have been previously exhausted by profuse hemorrhage, or some chronic disease, who are seriously injured by cautious depletion, local or general; and where death has followed the abstraction of sixteen or twenty ounces of blood from the arm, the fatal result may fairly be attributed to disease, and to the neglect of the remedy rather than to its abuse. In cases of intestinal irritation we have often found the local abstraction of blood followed by decided relief; and the same holds true with respect to the severe irregular uterine pains without inflammation which often occur subsequently to delivery, and do not yield to the ordinary means of treatment.

2. *Inflammation of the uterine appendages, ovary, fallopian tubes, and broad ligaments.*

We have met with one case only where the peritoneal covering of the uterus has been inflamed whilst the uterine appendages have remained free from disease, but frequently the peritoneum has been observed slightly affected, when the appendages of the uterus have been extensively disorganized. The surface of the broad ligaments, ovary, and fallopian tubes, when inflamed, have been found red and vascular, and partially or completely imbedded in lymph and pus. The loose extremities of the fallopian tubes have also been found of a deep red colour and softened, and deposits

of pus, in a diffused or circumscribed form, have taken place within these cavities, or in their sub-peritoneal tissues. Between the folds of the broad ligaments, effusions of serous or purulent fluids have also been noticed. Numerous important changes have likewise been observed in the structure of the ovary. Their peritoneal surface has often been seen red, vascular, and imbedded in lymph, without any visible alteration of their parenchymatous structure, or their whole volume has been greatly enlarged, swollen, red, and pulpy; blood has been effused into the vesicles of De Graaf or around them, and circumscribed deposits of pus have been found dispersed throughout the substance of the enlarged ovary. In several cases which have come under our observation, the entire structure of the ovary has been reduced to a vascular pulp, all traces of their natural organization being imperceptible.

The ovary appeared in one instance which we observed to be converted into a large purulent cyst, which had contracted adhesions with the abdominal parietes, and discharged its contents exteriorly through an ulcerated opening. In another case which proved fatal, the inflamed uterine appendages, agglutinated together by lymph, had contracted adhesions with the peritoneum at the brim of the pelvis, the inflammation having extended to the cellular membrane exterior to the peritoneum, and given rise to an extensive purulent deposit in the course of the psoas and iliacus internus muscles, as takes place in lumbar abscess.

In three other individuals, who ultimately recovered, the purulent matter formed along the brim of the pelvis made its way under Poupert's ligament to the top of the thigh, and escaped through an opening formed in that region. In all of these cases contraction of the thigh on the trunk took place, which remained for several months, but disappeared after recovery. The observations of MM. Husson and Dance prove that this is a frequent and often fatal termination of inflammation of the peritoneal coat of the uterus and its appendages.* In a woman who had a severe attack of inflammation of the right uterine appendages, a few days after delivery, the uterus remained low down in the pelvis, and was immovably fixed to the right side by extensive adhesions.

Inflammation of the uterine appendages being generally combined with peritonitis to a greater or less extent, it is often difficult to establish a diagnosis between these varieties of uterine inflammation. The pain is generally less acute than in peritonitis, and is principally seated in one or other of the iliac fossæ, extending from them to the loins, anus, and thighs. On pressure, the morbid sensibility will be found to exist chiefly in the lateral parts of the hypogastrium. The constitutional symptoms at the onset of the attack do not materially differ from those which mark the

* *Répertoire Générale d'Anatomie, &c. Paris, 1827, tom. iv. p. 74.*

accession of peritonitis, being often accompanied with strong febrile reaction, which passes speedily away, and is succeeded by prostration of strength and the other changes which characterize inflammation of the muscular and mucous tissues of the uterus.

3. *Inflammation and softening of the muscular and internal coats of the uterus.*

In two cases observed by us, the lining membrane of the uterus had become soft, flocculent, and completely disorganized, like the mucous coat of the stomach and intestines in certain inflammatory diseases. In other cases not only has the internal coat been inflamed, but the muscular tissue, to a considerable depth, or even through its entire substance, has been of a dark purple, greyish, or yellowish hue, and so softened in texture as to be torn by the gentlest efforts made in removing the parts from the body.

The peritoneum covering the inflamed portion of the muscular coat of the uterus has also been affected, and lymph has been thrown out over its surface as in simple peritonitis, or the peritoneum has become of a yellow, red, or livid colour, where no albumen has been deposited on its surface. The peritoneum has also been softened where the subjacent muscular tissue has been little affected, though more frequently there has been extensive disorganization of this latter tissue without a corresponding lesion of the peritoneum. In some cases the inflammation has affected the greater part of the muscular structure of the organ; in others it has affected only the cervix of the uterus, or the part where the placenta had adhered, and the natural appearance of the muscular fibre has been lost. In other instances deposits of pus have been observed, either immediately under the peritoneum or between the fibres of the proper tissue of the uterus.

In the different works on puerperal fever published in this country, this rapid and fatal variety of uterine inflammation has scarcely been noticed, though it has been accurately described by several German and French pathologists. Astruc, Vigarou, and Primrose state that the uterus is liable to be attacked with gangrene and sphacelus; and other authors, particularly Pouteau and Gastellier, have recorded cases where gangrene of the uterus followed acute inflammation of the organ. Boër* has described this affection under the term "putrescence" of the uterus, and has observed its frequent occurrence in particular epidemics. Luroth† and Danyau‡ have more recently published detailed accounts of this destructive disease. Among the two hundred and twenty-two fatal cases of puerperal fever observed by M. Tonellè in the Maternité at Paris in 1829, there were forty-nine in which the muscular tissue of the uterus was found softened. M. Tonellè states that "softening of the uterus," after shewing itself frequently

in the first half of the year 1829, and particularly about January, disappeared entirely in the months of July and August, which were characterized in a remarkable manner by the frequency of uterine phlebitis. Afterwards it began to rage anew with great violence in September and October, and again disappeared in the last two months, during which time the mortality was inconsiderable.

That the destruction of the healthy organization of the proper and internal tissues of the uterus which we have described, is the consequence of an inflammatory process, and not of any peculiar specific action, as some pathologists have maintained, may be inferred not only from the symptoms which accompany the disease, and from the usual effects of inflammation of muscular tissue in other parts of the body, but from the frequent occurrence of this affection in combination with peritonitis, and the other varieties of uterine inflammation.

Pain of the hypogastrium, diminution or suppression of the lochial discharge, and rigors with rapid feeble pulse, are the most frequent symptoms of the disease. The countenance becomes pallid, and expressive of great anxiety and distress. There are often severe headach and delirium, and other symptoms of cerebral disturbance. The skin is hot and dry, and sometimes of a peculiar sallow tinge; the respiration hurried, with great prostration of strength. The tongue soon becomes foul, the lips covered with dark sordes, and occasional nausea and vomiting are experienced. The disease sometimes runs its course with great rapidity; at other times it does not terminate fatally before the end of the second week.

The diagnosis of this variety of uterine inflammation, particularly where it is complicated with peritonitis or phlebitis, which is frequently the case, is extremely difficult. The prostration of strength, the alteration of the features, which often exist from the commencement, the feebleness and rapidity of the pulse, the irregular fetid state of the lochia, are not such constant symptoms as to be considered pathognomonic, and they may arise from other causes. The most attentive consideration of the phenomena will only lead to a probability, not to a certainty as to the nature of the affection; and sometimes its existence cannot be determined during life. In all the cases of this affection which we have observed, the resources of nature and of art have proved equally unavailing in arresting its fatal course. The active inflammatory symptoms, which have usually manifested themselves at the commencement of the attack, have passed speedily away, whatever plan of treatment has been adopted, and have been rapidly succeeded by symptoms of exhaustion. Where the disease has not been complicated with inflammation of the other tissues of the uterus, the symptoms have not been such as to indicate the necessity for the employment of venesection; and in one case where a considerable quantity of blood was abstracted from the system, death soon followed. In other cases where an op-

† Répertoire Générale d'Anatomie, tom. v. p. 1.

‡ Archives Générales de Médecine, 1830.

posite plan of treatment was had recourse to, the fatal result seemed to be less speedy, though equally certain.

4. *Inflammation and suppuration of the absorbent vessels and veins of the uterus.*

It does not appear that any pathologist in this country had observed a case of inflamed absorbents of the uterus before the month of July, 1829, when a fatal example of this disease occurred in St. George's Hospital. A woman aged 30, in an advanced stage of pregnancy, was admitted into that hospital under the care of Mr. C. Hawkins, July the 1st, in consequence of sloughing of the skin over a diseased bursa of the patella. The removal of the bursa by an operation was followed by great constitutional disturbance, and on the 14th labour came on. Two days afterward, symptoms of uterine inflammation made their appearance, and on the 18th day death took place. The pain was relieved by bleeding, but she never rallied after the attack. On examination of the body some puriform lymph was found in the pelvis, but with no increase of vascularity in the peritoneum. In the broad ligaments some fluid was also effused, and on each side numerous large absorbent vessels were discovered passing up with the spermatic vessels to the receptacle of the chyle, which was unusually distended. All these vessels, and the reservoir itself, were quite filled with fluid pus; but that in the receptacle was mixed with lymph, so as to be more solid: the vessels themselves were firmer and thicker than usual. The thoracic duct above this part was quite healthy. The uterus was scarcely contracted, and the internal surface of the lower half was soft and shreddy, and in a state of slough. The upper part, where no pus was found externally, was also healthy, or nearly so, on its inner surface.*

Since the occurrence of the preceding fatal example of inflamed absorbents of the uterus, four similar cases have fallen under our observation, the histories of which are related in the paper on uterine inflammation in puerperal women.†

In the magnificent collection of pathological drawings at the London University, there are several in which Professor Carswell has represented the appearances which he observed in cases of inflammation and suppuration of the absorbents in the vicinity of the uterus, of the receptaculum chyli and thoracic duct. These beautiful drawings were made by Professor Carswell in Paris, and it has been proved by the researches of Tonellé and Dupley, that inflammation of the absorbents of the uterus, of the receptaculum chyli, and thoracic duct, occurs not unfrequently in puerperal women, and that it gives rise to the same constitutional disturbance as uterine phlebitis. It appears indeed that these varieties of uterine inflammation are frequently combined; and it is probable that in both the purulent fluid is conveyed by the absorbents and veins into the mass of blood circulating in the arteries and veins of the body.

The local symptoms of this affection are often so obscure as to escape detection during life, while the constitutional symptoms, which often resemble in a striking manner the effects produced by the introduction of specific poisons into the body, are so violent as to yield to no remedies, however early and vigorously employed.

Inflammation of the veins of the uterus.

Uterine phlebitis.—Inflammation of the venous system, although known to the older writers, was first fully described by Mr. J. Hunter in the first volume of the Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge. The presence of purulent fluid in the veins of the uterus subsequent to parturition, was observed soon after the publication of that essay by Mr. Wilson and Dr. J. Clarke, and Meckel, but none of these authors were aware of the important fact which has recently been illustrated by numerous observations, that a large proportion of the cases termed "low childbed fever," or "typhoid puerperal fever," arise from inflammation and formation of purulent matter in the uterine veins. Twenty-four examples of this most insidious and fatal disease have fallen under our own observation since the autumn of 1827, and from an examination of all these cases, and of those related by foreign authors, it appears that the symptoms of uterine phlebitis correspond in a striking manner with the symptoms assigned by the earlier writers to the "putrid puerperal fever," or "malignant forms of typhus" which occurs after delivery.

In women who have enjoyed good health during pregnancy, and in whom the process of parturition has been easily accomplished, uterine phlebitis occasionally commences within twenty-four hours after delivery, with pain, more or less acute, in the region of the uterus, accompanied or followed by a severe rigor, or a succession of rigors, a suppression of the lochial discharge, acceleration of the pulse, cephalalgia, or slight incoherence of intellect, with most distressing sensation of general uneasiness, and sometimes by nausea and vomiting. These symptoms, after a short duration, are succeeded by increased heat of the body, tremors of the muscles of the face and extremities, rapid feeble pulse, anxious and hurried respiration, great thirst, with brown dry tongue, and frequent vomiting of green-coloured matters. The sensorial functions usually become much affected, and there is a state of drowsy stupor or violent delirium and agitation, which is followed by symptoms of extreme exhaustion; the whole surface of the body not unfrequently assumes a deep and peculiar sallow or yellow colour; the abdomen sometimes becomes swollen and tympanitic, and some of the remote organs of the body, such as the lungs, heart, brain, liver, and spleen, or the articulations and cellular membrane of the extremities, suffer disorganization from congestion, or a rapid and destructive inflammation.

There is scarcely an organ of the body which has not been observed to become secondarily affected from suppuration of the uterine veins. The vessels of the brain sometimes become

* Med. Chir. Trans. vol. xv. p. 64.

† Ibid, vol. xvi. 54.

greatly congested, and lymph is effused upon the surface of the pia mater, or serum into the ventricles; portions of the brain have become softened and disorganized, or purulent infiltrations have taken place into the cerebral substance.

In other individuals, whose lungs had previously been healthy, a rapid and destructive inflammation of the pleura has taken place, or portions of the pulmonary texture have become condensed, of a dark red colour, or infiltrated with pus. In three cases, where there had only been obscure pain in the chest during life, with slight cough and dyspnoea, a copious effusion of lymph and serum was found to have taken place into the cavities of the thorax; the pleura was covered with false membranes, and portions of the lung had fallen into a state of complete gangrene. In one individual the pleura had given way by sloughing, and the right side of the chest was distended with air.

In uterine phlebitis, the mucous membrane lining the stomach has also been observed by M. Dance to have been reduced to the state of a diffuent pulp, and the substance of the spleen has been extensively softened and disorganized;* the eyes have also become suddenly affected with destructive inflammation, and the vision has been lost many days before the termination of life. In two cases which came under our care the conjunctiva of both eyes, without much pain, suddenly became intensely red, the cornea opaque and the eyelids much swollen, and under their lining membrane a large serous deposition took place; lymph and pus were also effused into the anterior chamber, and in one the cornea ultimately burst. In a case related by M. Cruveilhier, the nose became black and gangrenous, yet the patient recovered.

Deposits, or infiltrations of pus, of enormous extent, also take place into the cellular membrane, between the muscles of the extremities, and often in the neighbourhood of the joints; the cartilages of the joints themselves become ulcerated, and pus is formed within the capsular ligaments.

In other individuals, who have never been subject to attacks of rheumatism, severe pain is experienced in various parts of the body, more particularly in the joints and extremities, with an exhausting fever.

All these affections appear to have a common origin, and cannot be referred to any other cause than to the morbid condition of the veins of the uterus. The purulent or other secretions, formed by inflammation within the cavities of these vessels, probably produce the whole of the injurious effects now described, by entering the system and contaminating the mass of blood in like manner as poisons do when absorbed into the body.

In some cases, uterine phlebitis commences at a later period after delivery than above described, and in a much more obscure and insidious form, without pain or sense of uneasiness in the region of the uterus, or any other local

symptom by which the affection can be recognized. The uterus may return to the reduced volume it usually assumes after delivery; the lochial discharge may continue; and the inflammation and suppuration of the veins, which have caused the whole of the violent constitutional disturbance and destructive lesions in distant parts of the body, may have been wholly overlooked during life. In many cases which we have witnessed, this error was committed by the medical attendant, and stimulants were liberally administered to obviate the debility supposed to exist in a specific form without any local affection of the uterine organs.

Inflammation of veins rarely takes place in any part of the body where it cannot be referred to a wound or to some specific cause externally applied to the coats of the vessels. In uterine phlebitis the inflammation cannot, it is true, be invariably traced to the orifices of those veins where the placenta adhered to the inner surface of the uterus; yet it scarcely admits of doubt that the frequent occurrence of the disease is the effect of the orifices of these veins being left open after the separation of the placenta, by which a communication is indirectly established between the venous system and the atmospheric air in a manner somewhat analogous to what takes place in amputation and other extensive wounds. Such a condition of the uterine veins, in consequence of the separation of the placenta, must be favourable to the production of inflammation, and inflammation once excited is seldom limited to these orifices, but extends with greater or less rapidity along the continuous membrane of the uterine veins to the spermatic or hypogastric veins, and from thence to the vena cava and its principal branches, which return the blood from the lower extremities.*

The effects of inflammation in the uterine veins are the formation of adventitious membranes on their inner surface, and the deposition of coagula of lymph, or of purulent matter within their cavities.

Coagula of the fibrine of the blood, which often extend a considerable distance into the uterine veins, are formed in the orifices of these vessels after every labour, and are the principal means employed by nature for the permanent suppression of uterine hemorrhage. These may be distinctly perceived for a long period after delivery, and they have a form and colour different from the coagula produced by inflammation. In opening the body of a patient four weeks after confinement, we observed distinct traces of these coagula, partially absorbed, in the muscular substance of the uterus, at the part where the placenta had adhered.

The inflammation may be limited to the veins, but not unfrequently the muscular tissue contiguous to them participates in the inflam-

* Archives Générales de Médecine, tom. 18, 19, 20.

* A paper by the writer of this article on the structure of the human placenta and its connexion with the uterus, was recently published in the Philosophical Transactions, with the object of proving that no vessels pass from the uterus to cells in the placenta, as the Hunters supposed, and consequently that no great bloodvessels are lacerated in labour.

mation, and becomes of a dark red, or blackish brown colour, and of an unusually soft consistence. The peritoneal covering may also be affected, and the usual consequences of puerperal peritonitis then ensue.

The veins which return the blood from the uterus and its appendages may be either wholly or in part inflamed: generally, however, (and this is a circumstance in the history of uterine phlebitis deserving particular attention,) the inflammation attacks the spermatic veins alone, and for the most part the one only on that side of the uterus to which the placenta has been attached; and it may either confine itself to a small portion of the vessel, or extend throughout its whole course from the uterus to the vena cava. The usual consequences of inflammation of veins are then apparent, viz. injection and condensation of the cellular membrane in which they are imbedded, thickening, induration, and contraction of their coats, and the deposition of lymph mixed with pus and coagula of blood within their cavities.

The same is the case with regard to the hypogastric veins, one only being generally affected. These are, however, more rarely affected than the spermatic veins; and this would seem to depend on the latter veins being invariably employed to return the blood from that part of the uterus to which the placenta had been attached.

But inflammation having once begun, it is liable to spread continuously to the veins of the whole uterine system, to those of the ovaria, of the fallopian tubes and broad ligaments. The vena cava itself does not always escape, the inflammation spreading to it from the iliac or from the spermatic veins. This occurrence seldom takes place to a great extent through the medium of the spermatic, the inflammation usually terminating abruptly at the opening of the spermatic into it on the right side, or of the renal on the left. If it pursue, as it sometimes does, the direction of the kidneys, the substance of these organs, as well as their veins, may be involved in the disease.

When the inflammation affects the hypogastric veins, it may extend from these to the iliac and femoral veins, and thus give rise to all the phenomena observed in phlegmasia dolens.*

Uterine phlebitis would appear to result either from the mechanical injury inflicted by protracted labour, from the force required for the extraction of the placenta in uterine hemorrhage, from retained portions of placenta undergoing decomposition in the uterus, and from any of the causes which produce the other varieties of uterine inflammation.

Though a most dangerous disease, uterine phlebitis is not invariably fatal. That it often occurs in puerperal women where it is not suspected to exist during life, is demonstrated by the fact that in the spermatic and hypogastric veins of females advanced in life, calcareous concretions and various kinds of disor-

ganizations have frequently been observed, which must have been the consequence of attacks of acute inflammation at some remote period.

Causes of puerperal fever.—The causes of inflammation in the uterine organs in puerperal women are often involved in great obscurity. In some cases the inflammation is distinctly referable to the injury inflicted upon the uterus by severe, protracted, and instrumental labour, the forcible introduction of the hand into the uterus to rectify the position of the child, exposure to cold and moisture, and various irregularities of diet soon after delivery. But frequently it arises in the most malignant form where none of these causes have been applied, and where we are compelled to refer it to some peculiar noxious constitution of the atmosphere, or to the communication of contagious miasmata.

It is a point of great practical importance to determine how far contagion is to be considered as a cause of the disease. Dr. Hulme maintained that it was not more contagious than pleuritis, nephritis, or any other inflammatory disease. M. Tonellé, who has recorded the history of the most fatal epidemic which has ever occurred in Paris, asserts that the idea of contagion was clearly out of the question there, for in the Maternité the women who were newly delivered had each a separate apartment, and yet were attacked with the disease, while in the sick ward of the hospital no instance of the propagation of puerperal fever ever occurred.

The evidence of M. Dugès against the doctrine of contagion is not less strong, for he states that in numerous instances pregnant women have been placed in the Infirmary, where they were surrounded by cases of peritonitis without imbibing the germ of the disease, and that still more frequently he has seen women newly delivered brought with some other complaint into the infirmaries, who did not contract the reigning malady, notwithstanding the miasmata which surrounded them.

In no instance has he observed a midwife charged with the care of two women at the same time communicate peritonitis from a sick to a healthy individual, as is reported to have happened in London; and never has this inflammation been propagated from patient to patient in the wards set apart for the reception of healthy women.*

In the earlier descriptions, however, of uterine inflammation, it is referred not only to the corrupted atmosphere of hospitals, but also to contagion. In the Dublin Lying-in Hospital, the Edinburgh Infirmary, the General Lying-in Hospital at Vienna, and in most of those in this metropolis, it has raged as an epidemic at different periods with great violence, and has appeared to be propagated by contagion. Dr. Gordon of Aberdeen states that he had unquestionable proof that the cause of the disease was a specific contagion, and not owing to any noxious constitution of the atmosphere.

* *Baudelecque*, sur la péritonite puerpérale: 8vo. Paris, 1830.

* See the article PHLEGMASIA DOLENS.

The disease seized such women only as were visited or delivered by a physician, or taken care of by a nurse, who had previously attended patients affected with the disease. "I had abundant proofs," he observes, "that every person who had been with a patient in the puerperal fever, became charged with an atmosphere of infection, which was communicated to every pregnant woman who happened to come within its sphere."^{*}

Mr. Hey observes, "If the puerperal fever of Leeds was infectious, which by many it was thought to be, it was so in a very inferior degree to that at Aberdeen; for I have known instances of free communication, by the intervention of others, between women in labour or child-bed and those affected with the disease, without any bad consequence. And, on the contrary, in many cases of puerperal fever, no channel whatever was discoverable whereby the disease could have been conveyed."[†]

Dr. Armstrong observed that most of the cases at Sunderland (forty out of forty-three) occurred in the practice of one surgeon and his assistant. "It is hardly possible to prove," says Dr. J. Clarke, "that it is not infectious, but it has also arisen, as far as we can judge, as an original disease where there had been no communication with infected persons."[‡]

It is difficult to reconcile this conflicting evidence and the facts we have observed: though they have led us to adopt the opinion that the disease is sometimes communicable by contagion, yet they have not, perhaps, been sufficiently numerous and of so decisive a character as to dispel every doubt on the subject of its contagious or non-contagious nature. It is but proper to state that it has occurred in many cases in the most destructive form where the idea of contagion could not possibly be entertained.

In the last two weeks of September, 1827, five fatal cases of uterine inflammation came under our observation. All the individuals so attacked had been attended in labour by the same midwife, and no example of a febrile or inflammatory disease of a serious nature occurred during that period among the other patients of the Westminster General Dispensary, who had been attended by the other midwives belonging to the institution.

On the 16th of March, 1831, a medical practitioner, who resides in a populous parish in the outskirts of London, examined the body of a woman who had died a few days after delivery from inflammation of the peritoneal coat of the uterus. On the morning of the 17th of March, he was called to attend a private patient in labour, who was safely delivered on the same day. On the 19th she was attacked with the worst symptoms of uterine phlebitis, severe rigors, great distur-

bance of the cerebral functions, rapid feeble pulse, with acute pain of the hypogastrium, and peculiar sallow colour of the whole surface of the body. She died on the fourth day after the attack, the 22d of March, and between this period and the 6th of April this practitioner attended two other patients, both of whom were attacked with the same disease in a malignant form, and fell victims to it.

On the 30th of March it happened that the same gentleman was summoned to a patient, a robust young woman, seventeen years of age, affected with pleuritis, for which venesection was resorted to with immediate relief. On the 5th of April there was no appearance of inflammation around the puncture, which had been made in the median basilic vein, but there had been pain in the wound during the two preceding days. The inner surface of the arm from the elbow, nearly to the axilla, was now affected with erysipelatous inflammation. Alarming constitutional symptoms had manifested themselves. The pulse 160, the tongue dry; delirium had been observed in the night. On the evening of this day the inflammation had spread into the axilla. The arm was exquisitely painful; but in the vicinity of the wound, which had a healthy appearance, the colour of the skin was natural, and no hardness or pain was felt in the vein above the puncture. On the 6th patches of erysipelatous inflammation had appeared in various parts of the body; on the upper and inner surface of the left arm and in the sole of the left foot, all of which were acutely painful on pressure. The inflammation of the right arm had somewhat subsided. The pulse was 160, the tongue brown, dry, and furred. Restlessness, constant dozing, and incoherence. When roused, she was conscious. The countenance cold; heat of the surface irregular. On the 7th, pulse rapid; countenance anxious; teeth and lips covered with sordes; somnolence and delirium. The left arm above the elbow was acutely painful, and very much swollen. The right was but little painful, and the erysipelas had made no further progress. The patches of erysipelas on the forehead and sole of the foot had disappeared, but there was a slight blush of inflammation on the inner side of the calf of the left leg. The symptoms became aggravated, and she died on Saturday, the 9th of April.

The author of this article examined the body with Mr. Prout on the 11th, and the following morbid appearances were observed.

The wound in the median basilic vein was open, and its cavity was filled with purulent fluid. The coats of this vessel and of the basilic vein were thickened so as to resemble the coats of an artery. The inner surface of these veins was redder than natural, and at the upper part had lost its usual smoothness, but there was no lymph deposited upon it. The mouths of the veins entering the basilic were all closed up with firm coagula of blood or lymph. The cellular membrane along the inner surface of the arm was unusually vascular, and infiltrated with

serum. This infiltration was to a much greater extent along the situation of the erysipelatous inflammation of the left arm; but the veins of this arm were perfectly healthy.

In the autumn of 1829 a physician was present at the examination of the body of a woman who died soon after delivery from inflammation of the peritoneal and muscular tissues of the uterus. He dissected out the uterine organs, and after inspecting them carefully, assisted in sewing up the body. He had scarcely reached home when he was hastily summoned to attend a young lady in her first labour, who was safely delivered. In sixteen hours she was attacked with violent pain in the region of the uterus; unequivocal symptoms of uterine phlebitis soon after shewed themselves, and she narrowly escaped with her life.

In December, 1830, two patients in the British Lying-in Hospital, who had been attended by the same midwife, were both attacked with the disease on the same day, and both died from inflammation of the absorbents and deep-seated tissues of the uterus. Another patient was admitted into the hospital two days after the death of the last of these women, and was examined by the same midwife to ascertain if labour had commenced. The pains were false pains, but she remained from Saturday till the Monday in the expectation that labour would come on. The pains having left her, she returned home, and on the following day was suddenly taken in labour and safely delivered before she could set out for the hospital. She went on favourably for two days, and was then attacked with the worst symptoms of inflammation of the veins of the uterus, and died in thirty-six hours.

The following statement has lately been published by Mr. Robertson, of Manchester, in number 214 of the Medical Gazette, and it goes to support the opinion that puerperal fever is a contagious disease. From December 3d, 1830, to January 4th, 1831, a midwife attended thirty patients for a public charity; sixteen of these were attacked with puerperal fever, and they all ultimately died. In the same month three hundred and eighty women were delivered by midwives for the institution, but none of the other patients suffered in the slightest degree. Mr. Robertson states that these sixteen were all cases of inflammation of the peritoneal surface of the uterus, and that in no instance did he meet with inflammation of the veins of the uterus.

These facts point out the necessity of adopting every precaution to prevent the extension of the disease, by careful and repeated ablution, and changing the clothes after attending patients who are affected with it. They shew also, whether they be considered perfectly conclusive or not as to the communicability of the affection from person to person, that we ought not to expose ourselves beyond what is absolutely necessary in examining the bodies of those who have been cut off by the complaint. When post-mortem examinations are required,

they should be conducted by those who are not engaged in the practice of midwifery. We certainly owe it as a duty to our patients to act as if the contagion always existed.

Whatever conclusion we may arrive at as to the contagious or non-contagious character of the disease usually termed puerperal fever, it cannot affect the view which has now been taken of its proximate cause or essential nature, for the symptoms, morbid appearances, and influence of remedies, all incontrovertibly prove, whatever the nature of the remote cause may be, that it acts by exciting inflammation of the uterine organs.

With regard to the nature of this inflammation, it is difficult to determine whether it be of a common or specific kind. It certainly arises where individuals are not exposed to the ordinary causes of inflammation, and it often reigns as an epidemic, particularly in hospitals; and in this respect it resembles erysipelas, hospital-gangrene, and other specific inflammatory diseases, which are generally supposed to depend on a vitiated state of the atmosphere. Like these diseases, too, it ceases without any assignable cause, perhaps for several years, and then re-appears in the same establishments, and is attended with the same destructive consequences.

Sporadic cases of puerperal fever are met with in all seasons of the year and in all the different ranks of life, and the disease is sometimes not less destructive when occurring in this form than in hospitals during the prevalence of an epidemic.

Pouteau supposed the inflammation of the uterus to be of an erysipelatous nature, and the same opinion was maintained by Dr. Lowder and Drs. Home and Young of Edinburgh, who saw the disease in the lying-in wards of the Royal Infirmary. Dr. Gordon observed erysipelas to prevail extensively at Aberdeen in 1795, but he has not inferred from this circumstance that the peritoneal inflammation which he has so accurately described was of an erysipelatous kind, or different from common abdominal inflammation.

Dr. Abercrombie has lately described several cases of peritonitis which he considered to be allied to erysipelas. The principal pathological character of this affection noticed by him is, that it terminates chiefly by effusion of fluid, without much and often without any of that inflammatory and adhesive character of the disease in its more common form. Pinel, Bayle, Gasc, and Laennec, to whom we are so much indebted for the knowledge we possess of the anatomical characters of inflammation of the peritoneum, have traced no resemblance between the phenomena of puerperal peritonitis and erysipelatous inflammation, and it is still extremely doubtful if serous membranes are liable to attacks of erysipelas. Dr. Hodgkin has stated to us that the appearances after death in puerperal peritonitis do not differ from those observed in ordinary peritonitis in the male sex.

Dr. Whiting maintains, in his lectures, that

the uterine inflammation of puerperal women is essentially different from common inflammation, and that it is of an erysipelatous nature. To establish this doctrine, it is requisite that some decided difference should be perceptible in the products of the inflammation subsequent to delivery, in the changes of structure, in the progress of the symptoms, and the effects of the remedies employed. Of the numerous dissections which we have made of the bodies of those who have died from puerperal fever, we have not discovered in the morbid appearances any thing to justify this distinction. Instead of running a definite course in spite of the application of remedies, as erysipelas does when it appears on the external surface of the body, the inflammation of the peritoneum in puerperal women is in most cases completely cut short at the commencement, if the appropriate treatment be vigorously adopted. Erysipelas in other parts of the body cannot be cut short in this manner.

The following coincidence may seem, however, to prove that there is some connexion between erysipelas and puerperal fever. In the autumn of 1829, a short time before the epidemic broke out in the British Lying-in-Hospital, which led to its being closed for several months, two children died of erysipelas. Another fatal case occurred in the course of the epidemic, and on examining the abdomen we found the peritoneum extensively inflamed, with a copious effusion of sero-purulent fluid. A few days before the re-appearance of the disease in the hospital, in December, 1830, an infant died of erysipelas of the internal organs of generation and abdomen, and the same diseased state of the abdomen was observed. Another infant was attacked with gangrenous erysipelas of the extremity of the right fore-finger on the 28th of December, whose mother had been cut off on the 24th by uterine phlebitis.

Mr. Blagden has related to us a similar case which occurred in his practice. A midwife of the hospital had a severe attack of erysipelas of the face a few days after attending in labour a fatal case of inflammation of the absorbents and uterine appendages.

During the prevalence of the disease in the winter of 1831 and 1832, two children died from inflammation and suppuration of the umbilical vein, and in both there were patches of erysipelatous inflammation on different parts of the body. In none of the hospital attendants has erysipelas shown itself at any of the above periods, and cases of infantile erysipelas have repeatedly occurred at periods when there were no examples of puerperal fever.

Treatment.—Like inflammation of other organs of the body, that of the uterus varies greatly in severity in different cases. At some particular periods we have remarked the existence of a disposition to the disease in certain puerperal women, evinced by tenderness of the uterus on pressure, and by acceleration of the pulse, where inflammation has not been actually

developed, or where it has taken place in so slight a degree as to yield readily to the exhibition of opiates, and the application of hot fomentations and cataplasms to the hypogastrium. Some physicians, and more particularly the late Professor Chaussier, have been so convinced of the advantages and necessity of employing these remedies, with the view of preventing attacks of the disease, that they have caused all their patients recently delivered to take from time to time, and at intervals more or less distant, small doses of Dover's powder, and have applied emollient cataplasms to the region of the uterus.

In cases of intestinal irritation, after-pains, and various spasmodic affections of the uterus and abdominal viscera, this plan of treatment will prove successful. In slight inflammatory affections of other organs it is not unusual for the symptoms to subside without the employment of active remedies; and from what we have observed in many cases, it does not admit of a doubt that, in the milder varieties of inflammation of the uterus, a spontaneous solution of the disease not unfrequently takes place.

But where inflammation of the peritoneal coat of the uterus is fully developed, and where the affection occurs in a severe sporadic or epidemic form, the soothing plan of treatment will prove wholly insufficient to arrest its course, and unless bloodletting general and local, and other antiphlogistic remedies be early and vigorously employed, it will in most cases proceed to a fatal termination. In the treatment of puerperal fever, the great objects we are constantly to have in view are the following: first, to subdue the local inflammation of the uterine organs; and, secondly, to moderate the constitutional disturbance which it invariably produces. In fulfilling these indications no exclusive plan of treatment should be adopted, but we ought, according to the peculiarities of each case and stage of the disease, to employ bloodletting, mercury, opium, cathartics, diaphoretics, blisters, and whatever other means we can discover to possess an influence in controlling the disease.

In no inflammatory affection of the internal organs are the good effects of bloodletting, general and local, more strikingly displayed than in the first variety of uterine inflammation—peritonitis; but the results of our experience do not confirm the accuracy of the conclusions of some authors, that in all cases by the early employment of these means we can succeed in curing the disease. It is always an affection attended with great danger, and it not unfrequently runs its course rapidly to a fatal termination, in spite of the most prompt application of remedies.

When the symptoms of puerperal peritonitis manifest themselves as before described and in a violent form, twenty or twenty-four ounces of blood should be immediately abstracted from the arm by a large orifice, and while the patient has the shoulders and trunk considerably elevated in bed. We should not be deterred from

employing the lancet because the pulse is small and contracted, provided it does not exceed 110 or 115 pulsations in the minute; for in many cases the pulse has become fuller and stronger during the time the blood has been flowing or soon after, and there has been a marked relief from suffering. In all cases, if possible, a decided impression should be made upon the system, and where syncope or faintness follows the venesection, it increases the salutary effect. In no case of inflammation of the peritoneal surface of the uterus have we observed any bad consequence to result from depletion carried to this extent, and in many, from its early use, the force of the disease has at once been completely broken.

When the attack of inflammation is violent, and when the pain is but slightly relieved, the venesection should be followed without loss of time by the application of one, two, or three dozen of leeches to the hypogastrium, proportioning their number to the urgency of the symptoms. When the leeches have fallen off, the bleeding from their bites should be encouraged by warm fomentations or by a thin warm linseed-meal poultice applied to the hypogastrium. We have never observed poultices occasion uneasiness or an aggravation of the symptoms by their weight. Care should be taken to have them frequently renewed.

At the same time ten grains of calomel should be administered in combination with five grains of antimonial powder and gr. iſs or gr. ii. of opium, or with ten grains of Dover's powder; and this medicine should be repeated every three or four hours, until the symptoms begin to subside. Upwards of fifty grains of calomel have been given in many cases in this manner with decided benefit, and in two only out of one hundred and fifty-six patients has the mouth been severely affected. We have never seen the mercury in such large doses produce those symptoms of alarming weakness, and that tympanitic state of the abdomen with vomiting and great irritability of stomach, which some have represented. After the second dose of the calomel we have often exhibited with advantage a strong purgative enema, or a cathartic draught of senna and salts, repeating it also according to its effect. After the operation of the medicine in some cases, the pain of the uterus, which had been only relieved, has completely subsided.

There are few cases in which it is necessary to have recourse to a second bleeding from the arm; and where the propriety of this is indicated by a renewal of the acute pain, the quantity of blood taken away should not exceed $\text{℥}xii.$ or $\text{℥}xiv.$ However much the patient may complain of the uterine pain, if the pulse be above 120 and feeble, and if the powers of the constitution have been much reduced by the previous treatment, blood should not be drawn a second time from the arm. Should the pain continue undiminished in violence six or eight hours after the first bleeding, or still later, and the pulse be full and not very rapid, and the strength of the patient but little impaired, a second venesection, to the

extent above stated, may be ordered, not only with safety but with decided benefit. It ought, however, to be remembered that much greater caution is required in prescribing the second than the first bleeding in puerperal peritonitis; and where we are not fully convinced that it is absolutely necessary, it is better to repeat the leeching than to abstract blood again from the arm. In no case of peritonitis which has fallen under our care has it appeared necessary or safe to bleed from the arm a third time, and in a very large proportion of cases one bleeding only has been had recourse to.

After the violence of the attack has been subdued, it is proper to continue the use of the calomel, but in diminished doses. Five grains of calomel, combined with the same quantity of Dover's powder, should be given every six hours, and this should be continued until the mouth becomes affected, or until the uterine tenderness be relieved. The great object in the administration of mercury is to remove the congested and inflamed state of the vessels of the peritoneum, and to prevent the termination of the complaint by effusion of fluid, when all remedies are generally unavailing. In the epidemic which prevailed in the Maternité at Paris in 1829, mercury was not employed until the last stage of the disease; and it is to this neglect, and to the almost exclusive use of local bleeding and emetics in the first stage, when active antiphlogistic treatment only could have availed, that we are disposed to attribute in a considerable degree the frightful mortality which ensued.

Where the symptoms do not indicate an attack of a formidable nature, we ought not to carry depletion so far, or to employ mercury and opium in the doses we have now recommended. In many of the cases which we have treated, one general bleeding has proved sufficient to overcome the disease, and in many the application of leeches alone, with five grains of submuriate of mercury and an equal quantity of antimonial powder, or Dover's powder, with cathartics, have subdued the complaint.

Other means, besides those now described, have been recommended by different authors in the treatment of puerperal fever, such as *oleum terebinthinæ*, *ipæcacuan*, *digitalis*, *colchicum*, and camphor.

Since the oil of turpentine was introduced into practice by Dr. Brenan, the most contradictory statements have been published respecting its effects. In a paper published in the Dublin Hospital Reports, Dr. Douglas observes that in the epidemical and contagious puerperal fever, $\text{℥}iii.$ of the *ol. terebinth.*, with an equal quantity of syrup and $\text{℥}vi.$ of water, should be given three or four hours after the exhibition of the first dose of the calomel; and that after the lapse of another hour this should be followed by an ounce of castor oil, or some other briskly purgative medicine. In some instances the oil of turpentine and castor oil may be combined in one draught. The internal use of turpentine is not to be repeated more than twice in any case whatever. "In

several cases," Dr. Douglas adds, "where the debility is very considerable, the local bleeding may also be omitted; and in this case a flannel cloth, steeped in oil of turpentine, should be applied to the abdomen, and allowed to remain on for the space of fifteen minutes. This external application of turpentine, without either its internal use or the aid of bloodletting, I have frequently experienced to be entirely efficacious in curing puerperal attacks; and although I have hitherto omitted to speak of turpentine for the cure of the other varieties of this disease, yet I would not feel as if I were doing justice to the community if I did not distinctly state that I consider it, when judiciously administered, more generally suitable and more effectually remedial than any other medicine yet proposed. I can safely aver I have seen women recover apparently by its influence from an almost hopeless condition, certainly after every hope of recovery under ordinary treatment had been relinquished."

We have not ventured to prescribe in many instances the internal use of *ol. terebinth.*, either in the superficial or deep-seated inflammatory affections of the uterus; but whenever this has been done, it has not only produced a renewal of the pain, but has excited the most distressing nausea and sickness. The results of our own observations and those of the most accurate observers in this country coincide very nearly with those which are described as having taken place in the practice of Dr. Joseph Clarke: "In addition to the usual routine of practice," he observes in his letter to Dr. Armstrong, "numerous trials were made of the rectified oil of turpentine, in doses of from six to eight drachms, sometimes in plain water, sometimes combined with an equal quantity of castor oil. The first few doses were generally agreeable to the patient, and seemed to alleviate pain. By a few repetitions it became extremely nauseous, and several patients declared 'they would rather die than repeat the dose.' In more than twenty trials of this kind not a single patient recovered."

In favour of the use of *digitalis* and *colchicum* in puerperal fever, little evidence that is satisfactory has hitherto been adduced.

Emetics.—Willis, White, and other physicians employed emetics, and more particularly ipecacuan, in the treatment of puerperal fever, before the year 1782, when Doulcet recommended the exclusive use of these remedies at the Hôtel Dieu. Most exaggerated reports of the success of his method of treatment were speedily propagated throughout Europe, and many were disposed to consider the results at the Hôtel Dieu as affording unequivocal proofs of the power of emetics to arrest the progress of the disease when occurring in the most malignant forms. Two hundred women were represented as having been saved to society in the course of one epidemic in Paris, by the administration of ipecacuan at the onset of the attack. It appears, however, from the statement of Alphonse le Roi, that the recovery of so many individuals was attributed, without any just ground, to the peculiar

treatment adopted; for the employment of ipecacuan and *Kermes mineral*, according to him, was commenced by Doulcet in the lying-in wards of the Hôtel Dieu when the epidemic was ceasing, but these means were found wholly inefficacious in the months of November and December, and at the beginning of the following year, when the mortality was greater than in 1780, before the remedy of Doulcet was known. M. Tenon affirms that in 1786 the complicated puerperal fever was curable by no means then discovered.

From the intense pain of the abdomen, aggravated by the slightest pressure of the hand or by compression of the abdominal muscles, and from the early occurrence of nausea and vomiting in the worst cases of the disease, emetics obviously appear to be little calculated for the relief of the symptoms, and few enlightened practitioners have employed them in this country for the last forty years. Some have gone so far indeed as to declare that they are sufficient to produce inflammation where it does not already exist, and that their employment is not only useless, but dangerous and absurd.

Several distinguished continental physicians, as Hufeland, Oslander, and Desormeaux, have, however, continued to employ emetics in the treatment of puerperal fever, and have supposed that they derived benefit from their use. M. Tonellè states that M. Desormeaux first made trial of them about the end of 1828, and that great advantage resulted from it. During the greater part of the following year they were again employed, but they succeeded in only a few isolated cases, and most frequently they entirely failed; they never, however, appeared to produce any aggravation of the pain or other symptoms. A new trial was made of them after this, and they were again followed by the most happy results. At the commencement of September, 1829, in the course of a fatal epidemic, and during a cold and moist season, emetics were again had recourse to; and for the two months during which this treatment was pursued, all the sick were not relieved, but a great number were delivered from their sufferings by enchantment, and for an instant there seemed to be a renewal of that brilliant success which had followed the adoption of this method by Doulcet and the physicians of the Hôtel Dieu. But at the end of October emetics gradually lost their influence; and towards the middle of November no advantage whatever was derived from them. In some of the successful cases related by M. Tonellè it ought to be observed, that forty leeches, and warm cataplasms, had been applied to the hypogastrium before the emetic was given, and in those where the relief was most decided the ipecacuan either produced a profuse perspiration, or acted freely upon the bowels, causing numerous, copious, and bilious alvine evacuations. It is highly probable, from the histories of the successful cases, that the effects of the treatment were referable rather to the action of the ipecacuan on the skin and intestines than on the stomach, for the relief experienced did not immediately follow the

vomiting. M. Tonellè admits that where effusion or suppuration had taken place, emetics were of no avail; and he also relates a number of cases in which the application of leeches to the hypogastrium and the employment of other antiphlogistic remedies were followed by speedy and complete relief where emetics had entirely failed to procure this.

In the milder forms of uterine inflammation, (and many of the cases related by Tonellè were of this description,) it is highly probable that an emetic, which would produce a sudden determination to the skin and a free action of the intestinal canal, would relieve the congested and inflamed state of the uterus, and thus cut short the disease. We have met with no case, however, in which we have considered it safe to administer emetics in any stage of the complaint, and we cannot conceive it possible for a case to occur in which the treatment should chiefly or exclusively be conducted upon the plan of Doucet.

The application of blisters to the hypogastrium and inside of the thighs and legs, has often been found advantageous where the pain of the hypogastrium has continued severe after the general and local bleeding. The external use of the oleum terebinthinæ has also in some cases unquestionably been followed by considerable relief of the pain; and its effect is more sudden than that of a blister.

Both general and local warm baths have been highly recommended by foreign practitioners. Where the skin was hot, the pain moderate, the strength of the patient not much depressed, the immersion of the whole body in warm water was often followed by a general perspiration and relief of all the symptoms. On the other hand they state, that when the pains were excessive, when there was great anxiety, a profuse general or partial perspiration, the strength much reduced, the respiration hurried and anxious, and the face red with intense headach, the patient could not support the warm bath, and derived no benefit whatever from it. The hip-bath was found more generally useful, and was employed almost indiscriminately by M. Desormeaux in all the different varieties of the disease.

Recolin, Dance, and Tonellè highly recommend the injection of warm water into the vagina and cavity of the uterus, by means of an elastic gum canula. These injections were repeated three or four times in the course of the day, and they not only washed away the putrid matters adhering to the internal surface of the organ, but they appeared to relieve the irritation and inflammation of the organ itself.

In many cases of puerperal fever severe irritation of the stomach supervenes in the progress of the disease, and this symptom seems occasionally to be aggravated by anodynes and saline effervescent draughts. A drachm of sub-carbonate of potash should be added to $\mathfrak{z}\text{v}$. of aquæ menth. virid. and an ounce of this mixture given every two or three hours. The effect of this medicine in allaying the irritability of the stomach has been very remarkable indeed in some cases related to us. Should

diarrhœa take place spontaneously, or result from the use of the mercury, it must be moderated by opium. The starch and laudanum glyster is by far the best mode of administering the anodyne.

During the active stage of the complaint, cinchona, camphor, and stimulants are inapplicable; but when the inflammatory symptoms have been subdued, and the patient is left in a state of great exhaustion, quinine, ammonia, wine, and other stimulants sometimes produce the happiest effects in rousing the powers of the system. We cannot too strongly urge the necessity of continuing to employ these remedies, and whatever else is judged useful, whilst the slightest hope of recovery can be entertained. Some women have been restored to health where the pulse had risen to 160, and had become so feeble as scarcely to be felt at the wrist, where there has been constant delirium for many hours, and the most alarming prostration of strength. Recovery has even taken place in some cases where the abdomen has become tympanitic, and effusion to a considerable extent has taken place into the abdominal cavity. In no acute disease is it of greater consequence than in this now under consideration, that the patient should be visited by the medical attendant at short intervals, and that the effects of the remedies he prescribes should be narrowly watched.

With regard to the treatment of inflammation of the uterine appendages and of the deeper-seated tissues of the uterus itself, whether of the absorbents, veins, or of the muscular structure, the symptoms from the commencement are generally those which contraindicate the use of general bloodletting. In cases where the reaction at the invasion of the disease has been violent, and venesection has been employed, the relief obtained has only been temporary, if at all experienced, and in some instances the abstraction of only a few ounces of blood from the arm has produced alarming syncope. Where the local pain is severe, leeches and warm fomentations seem to be the appropriate remedies; but as far as our own observations go, we are in possession of no remedial means which effectually controul those varieties of inflammation of the deeper-seated structures of the uterus which we have attempted to describe. The French physicians are, however, of a contrary opinion, and are satisfied that we possess a powerful remedy, even in the worst cases, in mercury, employed so as to excite salivation. In several cases of uterine phlebitis we have pushed this remedy by inunction to a great extent, and brought the system under the influence of mercury in less than twenty-four hours; yet the progress of the symptoms was not arrested, and the patients died, as others had done where the remedy had not been administered. In other cases we have employed mercury to a great extent internally, without the slightest benefit; and it may justly be doubted, from the results of M. Desormeaux's practice, whether or not it possesses the influence M. Tonellè supposes, for of forty-three cases where mercury was used as the chief

remedy, only fourteen recovered. In the latter stages of inflammation of the deep-seated structures of the uterus, the great depression of the powers of the system renders the liberal administration of stimulants absolutely necessary, and in several cases of phlebitis the life of the patient appeared to be preserved by them.

The importance of the prophylactic treatment is rendered obvious by the preceding observations. A puerperal woman ought to be as careful of herself for ten days after delivery as an individual who is recovering from an attack of continued fever or inflammation of some important viscus. While the uterus can be felt above the brim of the pelvis, and the lochial discharge continues to flow, the most fatal consequences may result from exposure to fatigue or cold, and the slightest imprudence in diet. The administration of acrid cathartics soon after delivery should always be avoided, and no unnecessary pressure of the abdomen should be made. The greatest care should also be taken by the practitioner, in performing the operations of midwifery, to avoid inflicting an injury on the soft parts of the mother. The hand ought not to be passed into the cavity of the uterus but with the utmost gentleness, when the introduction of it is required to alter the position of the fœtus, or to withdraw the placenta; and portions of placenta should be prevented from remaining and undergoing decomposition in the uterus. It is impossible too strongly to condemn the practice recently recommended, in cases of flooding after the expulsion of the placenta, of passing the hand into the uterus for the purpose of compressing the orifices of the uterine sinuses where the placenta had adhered.

We cannot conclude this subject, which is unquestionably the most important in obstetrical medicine, without pointing out the necessity which there exists for a full investigation of the means best calculated to prevent the occurrence of uterine inflammation in lying-in hospitals, where its dreadful fatality has been recorded by all writers since the foundation of these institutions. From the registers of the British Lying-in Hospital, the Maternité of Paris, the Dublin Lying-in Hospital, and the tables of M. De Châteauneuf, it is proved that the average rate of mortality greatly exceeds that of establishments where individuals are attended at their habitations; and if it should ultimately appear that all precautions are unavailing in diminishing the numbers attacked by the disease, it will become a subject deserving of the most serious consideration on the ground of humanity, whether lying-in hospitals should not be considered rather injurious than beneficial to society. From what has fallen under our observation in the British Lying-in Hospital and other similar institutions in the metropolis, where the utmost attention is paid to ventilation and cleanliness, and where the wards are not overcrowded with patients, we cannot hesitate to express our decided conviction that by no means hitherto discovered can the frequent and fatal recurrence of the disease be prevented, and that the loss

of human life thereby occasioned completely defeats the objects of their benevolent founders and supporters.

(Robert Lee.)

YELLOW FEVER; Kendal's fever; Bilious remitting yellow fever; Bulam fever; Coup de barre; Mul de Siam; Fièvre Matorote; Fièvre Amaril; Vomito prieto; Vomito negro; Fiebre Amarilla; Nova pestis; Typhus icterodes; Typhus cum flavedine cutis, &c. &c.

The anomalies which this disease has been observed to present,—the absence, under the observation of one medical man, of some of the symptoms which during another epidemic had been well marked,—the fact of practitioners having observed that certain symptoms, prominent during one period of an epidemic, have at another period been totally absent;—the fact, too, of patients in the very same ward of an hospital being frequently found to labour under symptoms so variously grouped as to lead an inexperienced practitioner to believe that he had before him three or four diseases bearing little affinity to each other;—all these circumstances have thrown difficulties in the way of this disease having had a place assigned to it in nosological arrangements free from objections.

By some, accordingly, the yellow fever has been classed with continued fevers, the symptoms not having appeared to them to correspond with those laid down by nosologists as characterising remittents; while, according to the statements of others, of whose accuracy of observation there cannot be a doubt, the disease has assumed the most unequivocal remittent form: indeed, as will hereafter be shewn, there is very respectable evidence in proof of its having, on some rare occasions, assumed even the character of intermittents.

This is not the place to attempt defining what constitutes, rigorously, remittent fever: it is plain that in most countries the opinions of medical men are at variance upon the subject. The remarks of close observers go to prove how frequently remittents may be masked so as to mislead us, if not very much on our guard, as to their true character.

Those therefore cannot, with justice, be accused of much inaccuracy, who, confining themselves probably to their own field of observation, have looked upon yellow fever as belonging to the class of continued fevers; but it is important to shew whether those are right who maintain that the disease bears no affinity whatever to remittents, and that it *never* assumes any other than the continued form. On this point it cannot be necessary to quote more than a few authorities of respectability. Dr. Rush, from his extensive experience at Philadelphia towards the close of the last century, may be considered as entitled to the first place; and in his account of the epidemics of 1793 and 1794, he distinctly notices remissions in several pages:—"The remissions were more evident in this than in the common bilious fever. They generally occurred in the afternoon."* "It,"

* Account of Epid. of 1793, p. 79.

speaking of delirium, "alternated in some cases with the exacerbations and remissions of the fever."^{*} Speaking of the second class of this fever, he says that it was attended "with obvious remissions."[†] At p. 45 of his account of the epidemic of 1794, he says that the disease "appeared most frequently in the form of a remittent. The exacerbations occurred most commonly in the evening." In another passage, often quoted, "Never has the unity of our autumnal fever been more clearly demonstrated than in our present epidemic. Its principal grades, viz. the intermittent, the mild remittent, the inflammatory bilious fever, and the malignant yellow fever, have all run into each other in many instances. A tertian has ended in death with black vomiting, and a fever, with the face and eyes suffused with blood, has ended in a quotidian which has yielded to a few doses of bark."[‡] In an official report from Mr. Campbell, of the army medical department, dated from Montserrat, in 1825, he gives as his reasons for thinking that the remittents, &c. of the West Indies are grades of the same disease, that during a yellow-fever epidemic at Barbadoes in 1821, he observed "the most marked difference in the type and symptoms of cases of patients from the same barrack or hut, where not the slightest doubt could be entertained of the disease being produced in both instances by one and the same morbid cause, yet so modified by physical causes, connected with the patient, as to appear quite different diseases, and certainly requiring different modes of treatment." The frequent occurrence of yellow fever in certain parts of Spain entitles the statements of the medical men of that country to great consideration on the point in question. To begin with the late Dr. Arejula, who was so familiar with yellow fever as it appeared in most of the epidemics which have occurred in Spain within the last half century,—the writer of this article has been repeatedly informed by him that the disease frequently assumed the most marked remittent form. In his description of the Malaga epidemic of 1803,§ he tells us that the bark was found useful during the *remissions*. At p. 71 he is clear on the subject of remissions; and at p. 139, informs us that the disease "without doubt deserves the name of remittent fever."^{||} He even says, when describing a black-vomit epidemic, "the termination of our remittent in *intermittent*, which also occurred in some instances at the close of the epidemic, was an indication that the disease was about to be extinguished." The recorded opinions of Dr. Velasquez of Seville are fully in corroboration of the statements of Arejula. The following physicians were contemporaries of the latter gentleman, and had witnessed some of the yellow-fever epidemics of Spain: Dr. Balmis, who called

the disease, as it presented itself during the Cadiz epidemic of 1800, "a putrid malignant remittent;" Dr. Flores Moreno, who describes in his work "accessions and remissions;" Dr. Alfonso de Maria of Cadiz, who is a state pensioner in consideration of his services during some of the epidemics of Spain, says, "when the yellow fever degenerated into intermittent." In the third volume of Hurtado's *Decadas*, published at Madrid, may be found a memoir relative to one of the Seville epidemics, with the signatures attached of Drs. Gabriel Rodriguez, Serafin, Adame, Velasquez, and Chichon, to the effect that "sometimes, though rarely, the fever presented itself following the type of an intermittent."^{**} In the *Trozos ineditos* of Dr. Salva, professor of medicine at Barcelona, evidence is to be found of the disease having been observed to assume the remittent form. In conclusion of this part of the subject it may be stated that the records of the Gibraltar yellow-fever epidemics furnish the following names in support of the fact that remissions not unfrequently take place in this disease,—Drs. McMillin and Browne, Messrs. Sproule, Wild, Martindale, Amiel, Daw, Donnett, Humphries, Lee, and Hugh Fraser.

History of the disease.—Previous to entering into details, it may once for all be stated that a disease is here understood in which, along with other symptoms hereafter to be referred to, yellowness of the skin, partial or general, and, towards the fatal termination, vomiting of a black or dark-brown fluid, are frequent, though by no means constant, occurrences. As it will be necessary to refer frequently to the yellow-fever epidemics of Spain, and as, notwithstanding all that has been written upon the subject, the identity of yellow fever, as it has appeared in that country, with the black-vomit fever of the West Indies and North America, has been denied, so late as 1828, by a French physician (Dr. Rocheaux), who went to investigate the Barcelona epidemic of 1821, it may be proper here to premise that the *perfect identity* of the disease has been admitted to have been established beyond all doubt, at Gibraltar in 1828, as will be shewn further on.

Among writers on yellow fever, of different nations, the names of respectable men will be found who maintain the doctrine that this disease has only made its appearance in modern times on the continent of America, in the West India islands, and certain parts of Europe. In opposition to this it has been shewn by others, that though in former ages, as in modern times, this disease may not have been observed to prevail epidemically in that part of the neighbourhood of the Mediterranean in which Hippocrates practised, it is not the less true that this close observer had been familiar with a fever in which the two symptoms considered by most writers as characterising the disease, (yellowness of skin and black vomit) were sometimes present. Respecting black vomit, held as being so peculiarly diagnostic, Hippo-

|| "Merece sin duda el nombre de calentura remittente."

** "Alguna vez, aunque rara, se presenta la calentura siguiendo el tipo de intermitente."

crates says, in the twelfth section of his prognostics, that if the matter vomited, in the form of fever which he is describing, be of a black colour, it betokens ill. In the first section of his prognostics, vomiting of a black fluid is mentioned as one of the most fatal symptoms; and in the fourth section of the same book this is pointed out by him as indicative of a high degree of malignancy.

We are reminded by Humboldt that the period of the first description of a disease furnishes no evidence of its having only then for the first time appeared; and the *ensemble* of the symptoms of yellow fever being perhaps only to be found fully and accurately detailed by writers of the last century, will scarcely be considered as furnishing conclusive evidence of the non-existence of similar epidemics at periods more remote. Owing to the state of medicine in former ages, and to the fact of practitioners having been so few that the sick were not unfrequently wholly destitute of aid, the exact nature of many epidemics which reigned from time to time, under the names of pest, pestilential disease, black death, yellow death, &c. has not been handed down to us. We have a remarkable proof of this in epidemics which from time to time prevailed in this country formerly, under the name of sweating sickness; for the accounts of that disease are quite unsatisfactory as to its nature. To admit that all epidemics of former ages, within certain parallels of latitude, and termed pests or plagues, were of the character of true plague, while all the epidemic fevers of modern times, which have so frequently afflicted the inhabitants of the same latitudes, have not possessed the characters of plague, but those of yellow fever, would be admitting what is but little conformable to the usual course of nature. Père Dutertre, one of the oldest writers on the yellow fever of the West Indies, employs the term *peste*, when detailing symptoms not corresponding with those of plague, but such as peculiarly belong to yellow fever.

To give here even but a partial view of the arguments employed by various British writers in support of and against the statement of the yellow fever having been imported into the West India islands for the first time in 1793, would occupy more space than could with any propriety be devoted to the point. Its importation into the island of Granada in the year in question rested chiefly on the authority of the late Dr. Chisholm, who believed that he had traced, with sufficient accuracy, the origin of the fever to the ship Hankey, which had lately arrived from the island of Bulam, situated on the west coast of Africa. This statement of the importation into the West Indies of a "*nova pestis*," as it was then called, has since given rise to much controversy; but those who consult Bancroft's Essay on Yellow Fever, and a small treatise on the disease published in 1818 by Dr. James Veitch, an experienced naval surgeon, will find details of a very interesting nature, which go to prove that on the occasion in question Dr. Chisholm had certainly proceeded on erroneous data. Indeed there can-

not be a doubt that, had he been better acquainted with the history of the diseases of the part of the world in which he then served, Dr. Chisholm could never have adopted the very erroneous opinion that the disease which he describes as so malignant, was one possessing new characters; for it is established by authentic historical proofs, that, long before the year 1793, a similar disease had made frequent ravages in the West Indies, as appears from accounts by Ligon, of an epidemic at Barbadoes in 1647;—by Hughes, of an epidemic in the same island in 1695; and again of epidemics there in 1720 and 1740, by Towne and Warren. Père Dutertre would seem to be the first by whom details of the symptoms and progress of this disease in the West India islands have been transmitted to us.* From the remarkable muscular pains often observed to take place in a patient labouring under an attack, as if from heavy blows, it was then called *coup de barre*; and Père Dutertre, considering it a new disease when he first saw it (1635), termed it "the pest unknown previously in these islands." He notices the yellowness of the skin particularly; and though he says in one part of his work that the disease was imported into the islands by "some ships," and in another page by a particular ship, La Bœuf, from Rochelle,—he says that those "were chiefly attacked who were employed in clearing the land in different islands, and were exposed to the poisonous vapours and exhalations."†

Père Labat, on landing at Martinique in 1649, found the disease raging in that island, and the monks belonging to the convent of his order suffered severely. He tells us in his work that he himself had the disease twice; that people were frequently attacked so suddenly and severely that they fell down in the streets; that hemorrhages from the several natural orifices, and even from the skin occurred; and that the disease usually proved fatal within five or six days. He states that the disease was called *maladie de Siam*, from the belief of its having been imported into Martinique by a ship of war, the *Oriflamme*, "which, coming from Siam with the *debris* of the establishments which had been at Mergay and Bancock, touched at Brazil, where she became infected with the disease which reigned there for seven or eight years."‡ This account of the introduction of the disease into Martinique relates to the year 1688, being some years before his arrival in that island; and his statement would seem to rest altogether on the belief then prevalent as to the circumstances.

At page 337 of Dr. Bancroft's Essay on Yellow Fever, we have evidence of the existence of the disease at St. Domingo in the year 1731; and, in subsequent pages, of its having prevailed there epidemically in 1733, 1734, 1739, 1740, 1741, and 1743. The insalubrity of that island was manifested soon

* Histoire Générale des Antilles.

† Ibid, p. 81, ed. in 4to.

‡ Nouveau Voyage aux îles de l'Amerique, tome 1.

after its discovery; for it appears that the sickness among his men gave Columbus great anxiety. It could scarcely have been expected that any thing very precise as to the nature of the disease from which they suffered should have been transmitted to us. The latest historian, Washington Irving, merely informs us that "when they fell ill their case soon became hopeless." Reasonable inferences may perhaps be drawn from passages in old Spanish historians. Oviedo, in his "*Historia General de las Indias*,"* speaks of a great mortality among Columbus's people in 1494, which he attributes to the humidity of the island. He says that those who returned to Spain were of a yellow or "saffron colour;" that people finding the country so unhealthy objected to go there;† and that in consequence three hundred convicts were at one time sent to St. Domingo. He adds, that if the king offered him the Indies he would not go there. M. Moreau de Jonnés‡ cites § one or two other passages from Oviedo on the same subject, which we have not been able to verify by a reference to the edition within our reach. Further details are given by Herrera (Madrid 1601) as to the violence, suddenness of attack, &c. of the disease which carried off so many of Columbus's men, at the time in question, in St. Domingo; and he refers to a letter|| written in 1498 by Columbus to the king of Spain, attributing the sickness of his men on their first arrival to peculiarities in the air and water.

Respecting the accounts of the existence of the yellow fever at remote periods on the American continent, it would appear that Dr. Fournier Pascey, of Paris, who for several years devoted much attention to all questions connected with the disease, considers it identical with a disease referred to by Ferreyra da Rosa, in his account of Pernambuco, printed at Lisbon in 1649. In the beginning of the last century the disease, from its appearance in various parts of Spanish America, under the name of *vomito prieto*, attracted much attention; and it is particularly referred to by the historian Ulloa, who resided for some years in that country. The word *prieto*, it may be remarked, is the Portuguese or nearly obsolete Spanish term for *black*: in Spain the word *negro* is now universally substituted. The first work *ex professo* on the black-vomit fever, as it appeared in South America, is probably a little pamphlet of sixty-two pages by a Dr. Gastelbondo, written at Carthagena (S. A.) in 1753, and printed at Madrid in 1755: he gives his experience of the disease during forty years; says, in the title-page, that he is about to write on a disease of frequent occurrence in that part of the world; mentions change of

climate and mode of living among the causes of the disease in new comers; and says that the natives of Carthagena, Vera-Cruz, &c. were not subject to attacks of the true black-vomit fever, though liable to the "*chapetonada*," a disease resembling it in some respects.

In North America the appearance of the yellow fever epidemically, at different times previous to 1793, seems unquestionable; and authorities may be cited for its appearance at Boston in 1693; at Philadelphia in 1695, 1741, 1751, and 1762; at Charlestown in 1695, 1732, 1739, 1745, and 1768; at New York in 1702; and in Virginia in 1744.

We come now to the history of yellow fever in that part of Europe where its frequent appearance epidemically, within the last half century, has so justly excited the attention of the profession and of those governments who rank the investigation of such subjects among their first duties. Some writers (among whom is Sir Gilbert Blane) have stated that the first appearance of yellow fever in Spain was at Cadiz in 1764; next in 1800 in the same city; and at Malaga, for the first time, in 1803. It seems strange that, with respect to Cadiz, those writers should have overlooked the remarkable epidemics at that place in the years 1730, 1731, and 1736, as recorded by different authorities; the two first being very particularly noticed by Villalba, in his curious work "*Epidemiologia Espanola*." It seems equally extraordinary that those writers should have overlooked the black-vomit epidemic which prevailed at Malaga in 1741, described by Dr. Rexano, and since frequently referred to by different authors. With respect to epidemics which are recorded as having frequently prevailed in Spain, previous to those of Cadiz and Malaga just referred to, many consider the evidence imperfect as to the disease having been, in any of them, similar in character to that under consideration; for in those days, as already remarked, all epidemics causing great mortality were called pests, or pestilential diseases. In epidemics called pests, recorded as having prevailed at Malaga in 1678 and 1679, two physicians, Drs. Checa and Molina, sent officially to inquire into the nature of the disease, pronounced it *not* plague. The writings of Spanish medical men being but little known to the profession at large, quotations from some of them on the present subject may be the more admissible. Dr. Hurtado of Madrid, one of the few modern physicians of Spain who have published their opinions freely on the subject of yellow fever, adduces proofs in support of the prevalence of the disease epidemically in former ages in that country. He quotes Dr. Garcia Suelto as being of his opinion that such epidemics appeared at periods much more remote than 1730, and cites him as stating that "the most distinguished men of the profession move as it were in a career new to them, but long known to Spaniards their countrymen. If the medical history of Spain had been more familiar to them, they would have availed themselves of the excellent descriptions and important illustrations to be

‡ A man of science, formerly a military man, who, since his service at Martinique in 1802, as aide-de-camp, has figured a good deal in the discussions relative to the contagion of yellow fever as well as spasmodic cholera, though not of the medical profession.

§ Monographie de la Fièvre jaune.

|| Book iii. ch. 15.

found in the work of Antonio Fonseca, on the pest and contagious diseases, and on the epidemic fever of 1621." Hurtado also quotes Sebastian Nuñez, Pablo Correa, Manuel de la Cerda, and others. The frequent application of the word *atrabilis* formerly to any dark fluid ejected from the stomach, tended, no doubt, to create obscurity as to the character of diseases; and in Spain, medical men, for want of a better name, sometimes employed the words *fiebre dudosa* (fever of a doubtful nature) when speaking of the epidemic disease. Escobar is quoted by Villalba respecting an epidemic which prevailed in Carthagea in the autumn of 1648; and in which, contrary to what they observed to take place in plague, was attributed to local causes. Escobar states that in his time the endemic fevers of Carthagea and Alicant sometimes became *pestilential* in the autumnal months. It appears from Villalba's work, that in 1648 other towns besides Carthagea, as Cadiz, Seville, Alicant, and Valencia, were afflicted by the epidemic; and it is remarkable that some of the writers of that period state that the disease *was carried to the West Indies* from one of those towns, from whence it was again brought back to Spain, and commenced fresh ravages at Barcelona, Girona, Tortosa, and "almost in every town in Catalonia." From this we may at least infer that, at the period mentioned, the identity of the Spanish and West India diseases was acknowledged. According to Villalba, three formidable epidemics took place in remote times at Barcelona within a period of eighteen years—one in 1497, another in 1501, and the third in 1515; and as they prevailed in the summer or autumnal months, their identity with the modern epidemics of Spain has been inferred. Villalba records an epidemic at Barcelona in 1589, which lasted from June to December,—the deaths up to the 20th October having been ten thousand nine hundred and thirty-five. On this occasion the resident physicians of Barcelona maintained that the disease *was not plague*. A Dr. Porcel wrote, in 1565, on an epidemic which prevailed at Saragossa in the preceding year, and which ended in the month of December. He states that the symptoms were sometimes very insidious; that the patient seemed to be going on well,—pulse natural, skin temperate, &c.—till the fourth day, when the countenance became altered, and faintings took place, followed commonly by death: he adds that sleeplessness, extreme anxiety, (the patient rolling about the bed,) peculiar pain in the region of the stomach, and vomiting of a fluid (which he calls *colera*) of various shades of colour, took place. He notes, moreover, that the countenance became livid and yellow, (*livido y amarilla*.) The work of a Dr. Andosilla is also cited, in which he speaks of a disease under the name of *peste*, which prevailed in some Spanish towns in the autumn of 1600. He visited those towns by order of his government, and describes the disease as not having the characters of plague, but others new to him. In 1649, a Dr. Morillo, who had been em-

ployed at Marbella and other towns in Andalusia during an epidemic, went also to Gibraltar in that year, to witness an epidemic there, which, according to an old Spanish history of Gibraltar, proved so fatal that the people, losing all confidence in human means, instituted processions to the neighbouring hermitage of St. Roque, which were kept up annually in the month of August, till the surrender of the garrison to the British in 1704. There is a record of that garrison having, in the autumn of 1727, lost five hundred men by fever, but the character of the disease is not described. By a document in our possession from Mr. Hill, deputy inspector-general of hospitals, and bearing date June 13, 1832, it appears that in 1798 the forty-eighth regiment, which was under the medical charge of that gentleman, arrived in Gibraltar from England, and that soon after a severe fever appeared among the men, which carried off about one hundred of them. This fever, which he says was confined to the recruits, of which there were great numbers, "Dr. Harness, then physician to Lord St. Vincent's fleet, and afterwards one of the commissioners to the Sick and Hurt Board, declared to be precisely the same he had seen in the West Indies." In Trotter's *Medicina Nautica* it is stated that 257 deaths from fever took place in the above garrison in 1800, among the military; the average annual mortality among the military there having been only thirty-eight. With respect to Gibraltar, therefore, these facts may perhaps be considered as sufficient to establish that, previous to the remarkable yellow-fever epidemic of 1804, the disease had made its appearance there to a formidable extent: indeed it is well known that, along that part of the Spanish coast, no other form of fever proves so fatal. It may be added that Dr. Monro says in his work on the diseases of armies, that, in 1799, a fever made its appearance at Gibraltar, which he considered similar to that of the West Indies.

As the profession generally cannot be aware of the several places in Spain in which yellow fever has prevailed, we may be permitted to place on record the following list of cities, towns, and villages in which it is admitted to have appeared since 1800:—

In Andalusia.

Cadiz.	Paterna de la Ribera.

In Guypuscoa, 1 (Passages.)
Total number of places, according to the best information, 89.

The above list is important, inasmuch as it must remove an impression that yellow fever has never appeared in more than a few places in Spain, and those sea-port towns. Among the places furthest from the coast where it has shewn itself, are,—Cordova, seventy miles in a direct line from the sea; Montilla and Ecija, about the same distance as Cordova; Ronda, sixty miles north of Gibraltar, and at an elevation above the sea of about four thousand feet; Granada, thirty-one miles in a direct line from the sea. In these places, as well as in a great majority of the other instances, the disease appeared to a limited extent only.

Respecting yellow-fever epidemics in other parts of Europe, that described by Palloni, Tomassini, and others, as having taken place at Leghorn in 1804, is the most remarkable. We have an account, by a Dr. Kennedy, of an epidemic at Lisbon in 1736; and from the symptoms there seems little reason to doubt of the identity of the disease with yellow fever. Professor Salva of Barcelona considers a fever

with yellow skin which prevailed very extensively in a district of the Canton of Berne, during a period of very extraordinary heat, in the year 1762, and of which there is some account in a volume of the proceedings of the French Academy of Sciences for 1763, as similar to the yellow fever of Spain. Some recognize this disease also in the fever with yellow skin, hemorrhages, &c. described by Frank as occurring in Hungary.

The existence of this fever with its characteristic group of symptoms, occasionally at points higher up the Mediterranean than those already mentioned, rests upon respectable authority: among others which might be quoted, Dr. Alexander, surgeon to His Majesty's forces, who has had ample experience of yellow fever in the West Indies, declares that he witnessed many deaths from the disease in Sicily, soon after the return of Sir John Stewart's army from Lower Calabria in 1806; and that while at this latter place, some cases occurred among our troops. The existence of sporadic cases of yellow fever with black vomit in England and France has been insisted upon by some persons: those referred to in the *Dictionnaire de Médecine*, vol. xxi. p. 17, as having occurred at Paris in the hot summer of 1822, seem most worthy of attention.

In turning to East India records, the mention, at p. 46 of the Bengal reports on cholera, of a fever with yellow skin, which occurred in that presidency in 1816, can hardly be held as conclusive. But we find, in a memoir by Mr. Walsh of the medical department of our army during the late Burmese war, that that gentleman, while in charge of cases of the fever prevalent in the army, was surprised by the sudden appearance of some with black vomit and yellow skin. It is recorded, as has been noticed by Dr. Johnson, in his work on tropical climates, that those symptoms appeared in a fever which prevailed in the hospitals at the Isle of Edam appropriated for the sick of the force employed for the reduction of Java in 1811.

At Sierra Leone this disease is recorded as having occurred, to a remarkable extent, in the year 1823.

Connected with the history of yellow fever, it is always considered a point of very great importance to ascertain whether it be a fact that, in those parts of the world where the disease is observed to prevail epidemically, sporadic cases have occurred in ordinary years. To the mass of evidence on this point, from the West Indies and America, not one word need be added in confirmation of this being the case in those places. In Europe a few only hold out against the statement:—in England, probably not more than two or three. But of late years so much attention has been paid to the subject, that unless people be prepared to prove that symptoms, grouped together in a certain order, in conjunction with similar *post-mortem* appearances, do not always constitute the same disease, it is quite idle longer to dispute the point. Among many other French physicians, who have paid great attention to the subject of yellow fever, and who have re-

cognised the existence of sporadic cases in Spain, are Drs. Pariset and Robert, leaders of the contagionists. In Spain we find the late Dr. Arejula, a leading contagionist in that country, and Dr. Flores Moreno, also a contagionist, admitting it freely in their works; besides Drs. Piguillem, Salva, and several other men of note. The writer of this article is in possession of such a body of evidence, drawn from registers and other authentic sources at Gibraltar, as would, of itself, place the matter beyond all doubt. In the month of April, 1829, the records of the civil hospital in that garrison were examined, and a certificate drawn up and signed by nine gentlemen, to the effect that thirty-eight cases, of which they found details duly recorded in non-epidemic years, were identical in character with the cases which occurred there during the epidemic of 1828. All those gentlemen had seen more or less of yellow fever, and some of them had witnessed two or three epidemics. There is, besides, further evidence in corroboration, by Dr. Gray, formerly physician to the Gibraltar naval hospital;* by Staff-Surgeon Glasse;† by the late Dr. Hennen, inspector of hospitals, in his official reports; by the testimony of medical officers of the Ordnance, the 12th, 23d, 43d, 64th, and 94th regiments, who saw several cases possessing the true character of yellow fever at Gibraltar, either before or since the epidemic of 1828.

The history of yellow fever cannot be dismissed without briefly touching upon its appearance from time to time on board of ships. It cannot be expected that where space is, as here, necessarily limited, all the cases of this kind of which records exist, should be noticed. In 1726 great havoc was made in the fleet of Admiral Hosier, lying off Portobello, by a disease alleged to have been yellow fever. In 1741, Admiral Vernon's fleet suffered from it off Carthage, (S. A.) In 1742, the disease broke out in the same fleet off Portobello. In 1776, the Spanish ships *Angel* and *Astrea* suffered from the disease on their way to the West Indies. It broke out in the squadron of the Spanish Admiral Solano, in 1783. In 1785, in the Spanish ship *Sn Il-defonso*. In 1793, in the *Sn Lorenzo*, one of the ships of the Spanish Admiral Aristobal, bound from Cadiz to the West Indies. In the same year in the squadron of the Spanish Admiral Borja. In 1794, on board His Majesty's ships *Bedford* and *Kent*. In 1795, on board the Hussar frigate on the American coast. In 1801, on board the ship *Penelope*, carrying Irish emigrants to New-York. In 1802, in a French fleet from Tarentum, bound to St. Domingo. In 1803, on board the *Hibbert* on her passage from Portsmouth to New-York. In 1805, in the fleet of the Spanish Admiral Gravina. In 1807, in the *Phebe* in the West Indies. In the same year in a French squadron in the bay of Cadiz. In 1808, on board the French brig of war, *Palinure*. In 1813, in an

English vessel which arrived at St. Domingo from England, as stated by Dr. Pinedo. In 1814, in a flotilla of Spanish revenue cruisers ("*guardacostas*."*) Since this period it appeared* in the following ships of war, on the West India station: *Iphigenia*, *Wasp*, *Tribune*, *Sapphires*, *Scout*, *Tamar*, *Bustard*, *Thracian*, *Rattlesnake*, *Lively*, *Isis*, *Scylla*, *Pyldes*, and *Ferret*. But the instances which of late years have attracted most attention, are those of the *Pyramus*, in 1822, in the West Indies;—of the *Bann*, in 1823, on the African station; of the Spanish merchant ship *Donostiarra*, in the same year, in the port of Passages in the Bay of Biscay; and of His Majesty's ship *Blossom*, in 1830, while engaged in surveying the Honduras coast.

Symptoms.—In no disease do symptoms appear to take a wider range than in yellow fever; and, on this account, it is usually considered necessary to speak of two or three, or even of four forms of the disease.

In the mildest form the febrile excitement may not proceed beyond that of mild synchus; indeed experience during epidemics warrants the conclusion that an individual, especially if a child, may pass through the disease with no more than a slight feeling of indisposition for a day or two. In epidemics of ordinary severity such mild attacks may occur in the proportion of one to ten or twelve of the severer grades; and their occurrence will usually be found more frequent as the end of the epidemic season approaches.

In a well-marked case, and in which premonitory symptoms (as *malaise* or slight head-ach) may or may not take place, the symptoms most commonly present are,—rigors, nausea, frontal, but especially supra-orbital head-ach, the conjunctivæ injected, and the eyes have a peculiarly brilliant appearance; aching of the calves of the legs and of the knees, more marked than in other fevers, and the rachialgia often quite intolerable. The loaded tongue, as if covered with paste, has been mentioned by authors; but, in our experience, a perfectly clean tongue has not unfrequently been observed in a most dangerous attack. There may be a remarkable trembling of this organ; or it will sometimes be swollen, and have its apex turned downwards. The most characteristic appearance, however, of the tongue, in yellow fever, is the pasty surface, with red edges and apex. In a young and vigorous subject, the heat of the skin may be of the pungent nature described by some writers on fever; but in yellow fever a temperate skin is far from being always an indication of a mild attack. An *impacted* state of the skin is always indicative of danger. Sensibility of the epigastrium frequently exists; but even in the severest cases free pressure can often be employed without an indication of pain being produced by it. Jactitation is a remarkable symptom: the patient tosses his head and limbs about incessantly, unable to procure sleep in any position, or relief from the feel-

* See Wilson on Yellow Fever, p. 92.

ing of distress by which he is oppressed. In other instances, the patient, while lying pretty tranquilly, starts when approached, and seems terrified when spoken to. He draws deep inspirations; and sometimes, though languid, he will beg to be allowed to get out of bed, in the hope of experiencing relief. From the commencement there is a tendency to costiveness; never, as far as we are aware, to an opposite state of the bowels. As the disease proceeds in its course, the irritability of the stomach usually becomes one of the most remarkable as well as indomitable of the symptoms:—there is often, indeed, little use in directing medicine or drinks, even of the most delicate kinds and in the smallest quantities, as all are instantly rejected; and, altogether without resources, we often find ourselves obliged to look on in the expectation of the arrival of a tranquil moment, when we may again venture on the exhibition of something. Our experience during two epidemics (one in the West Indies, and that of 1828 at Gibraltar) by no means bears out the statement of others as to the *bilious* appearance of what is vomited in the progress of this fever: after having paid the closest attention possible to this point, we must, on the contrary, state, that with the exception of the black-vomit stage, and at the very commencement of the attack, what is thrown up consists of the ingesta and a glairy fluid. Bile is also *usually* absent on an inspection of the stools and urine. But it must be recollected that we are speaking of a disease which, like spasmodic cholera, furnishes exceptions to almost every rule which can be laid down regarding it; and with respect to bile in the urine, we find it occur in some cases, as distinctly admitted by a commission of Seville physicians, in their report of the yellow-fever epidemic in that city in the year 1819.* They mention that they found the urine “yellow, and paper dipped into it was tinged the same colour.”

The stage of excitement, with occasional rigors, may vary as to duration, from forty-eight to seventy hours; when the pulse, which up to this time may have been full, rapid, and more or less firm, begins to give way; the eyes lose their brilliancy; the patient in some instances becomes so faint as to be unable to sit, unsupported, on the night-chair. The attack sometimes terminates fatally at the end of the third day; in which case we have quickly added to the foregoing symptoms, a peculiar acrid or *burning* sensation in the stomach extending not unfrequently to the œsophagus; the temperature of the surface, but especially of the extremities, falls rapidly; no urine is secreted; the stools may or may not be very dark; the features shrink; a distressing degree of singultus takes place; and finally, the black vomit. More commonly, however, the disease, in epidemics of ordinary severity, does not proceed so quickly to a fatal termination, but will extend to the fifth, sixth, or seventh day: indeed fatal terminations at periods much later

are not uncommon; and a few extending to the twelfth and fifteenth day have passed under our own observation. Yellowness of the skin, varying from the lightest to the deepest tinge, may occur as early as the third or fourth day; but it oftener occurs at a more advanced period. This yellowness is usually first perceptible in the line of the large vessels of the neck, next over the chest, and then over the whole body,* the adnatæ becoming, at the same time, more or less yellow. From about the fourth day hemorrhage, most commonly from the gums and nose, is liable to occur; but it has been observed to take place from every orifice of the body, and even from the skin, and from under the nails. As this stage proceeds, the tongue becomes so black, shrunk, and incrustated, that it has the appearance of having been seared with a hot iron; the pulse becomes more feeble, irregular, and occasionally intermits; the stools are dark and gelatinous in appearance; the singultus becomes most distressing; and, finally, when the symptoms follow this order, coma not unfrequently precedes death. From observations made during the last Gibraltar epidemic, it would appear that in those cases where copious hemorrhage takes place from any of the natural orifices, black vomit and suppression of urine are much less likely to occur.

Where neither yellowness nor hemorrhage supervene, we may have a different group of symptoms set in, which lead to a fatal termination in a shorter time. The countenance of the patient may not indicate great danger; but he is observed to lie, his limbs being uncovered, with his head hanging over the edge of the bed: he seems sensible when spoken to, and will assist to arrange the bed-clothes, which soon again become displaced. The tongue is dry, furred, and brown or yellow at its base; its papillæ are often separated in a remarkable manner, and deep fissures sometimes take place in its substance. The pulse is feeble and intermitting; the stools are usually dark. The irritability of the stomach is more remarkable in those cases. In some, slight spasmodic twitches about the mouth may be observed immediately preceding death. In a few instances trismus has occurred. In the *early part* of the last Gibraltar epidemic, besides singultus, suppression of urine, and black vomit, a very remarkable symptom sometimes took place in these cases a few hours before death; viz. a loud, incessant, and monotonous wailing, extremely distressing to all within hearing; the patient, during the time, lying covered up, apparently insensible to every thing, and incapable of replying distinctly to questions.

Another form is where the deadly nature of the attack seems to be marked in strong characters in the countenance of the patient from almost its very commencement. The features seem shrunk, *decomposed*; the face has a mottled or ash-coloured appearance. The look is sullen,

* In Dr. Bancroft's Essay some interesting remarks will be found on the yellowness of the skin in this fever.

* Hurtado's Decadas, vol. iii. p. 121.

and the eyes are of a dull-red colour. The tongue possesses in this, more frequently than in any other form, the appearance pointed out as being most characteristic of the disease. There is usually little or no vascular excitement, and the surface is temperate, — sometimes below the natural standard from the commencement of the attack. The patient will perhaps say that he does not feel much the matter, and will move about as we converse with him; indeed he often possesses a surprising degree of muscular energy. Here hiccup generally sets in soon, with lividity and coldness of the extremities, only equalled by that which occurs in the worst forms of cholera. The patient does not complain of being cold. In this state the pulse can scarcely be felt at the wrist; sometimes not at all. The stools are sometimes of a light colour, small in quantity, and lying flat in the vessel. The ears and extremities assume a leaden colour; suppression of urine takes place, and the black vomit, with the acrid sensation in the stomach, may quickly set in, which close the scene, not unfrequently within forty-eight hours. But where the two symptoms last mentioned do not occur, life may be protracted to three days; the extremities being for a great part of the time so cold and clammy as to give a shock to those who touch them; and though they lie seemingly ungoverned, the patient is able to move them as he may be ordered. He will lie quiet for hours perhaps, but obtains no sleep; and on being approached, the eyes are found wide open. When asked a question, he seems to understand its meaning, and usually gives a pertinent answer; but he is generally taciturn unless spoken to. In those cases we seldom find that there is any yellowness during the attack.

By a few authors on yellow fever two symptoms have been mentioned as liable to occur, which have not presented themselves under our observation, — intolerance of light and petechiæ. The following symptoms, occurring in typhus, are not, as far as we are aware, liable to present themselves in the disease of which we are treating: — meteorism; the eruption termed *sudamina*; the contraction of an upper extremity; tinnitus aurium; the involuntary passing of the fæces and urine; deafness; sores about the mouth. Bed sores are not liable to occur, as in other fevers in those cases where relapses take place, or where the disease runs a course of many days. Furious delirium is not liable to occur; and though mild delirium and coma not unfrequently take place, the mental faculties in a great proportion of the cases, remain entire to within a short time of the fatal termination. Excoriations, causing great distress, have been observed to take place on the scrotum, penis, and about the anus. The statement as to the occurrence of gangrene on blistered surfaces has in no one instance been verified in the experience of the writer of this article. In some cases he has met with hemorrhage from leech-bites, very difficult to suppress. Anthrax is stated by a few writers to have been occasionally met with in yellow fever.

Infiltration of venous blood into muscular parts has been noticed as occasionally occurring in the disease in the West Indies; and the epidemic of 1828 at Gibraltar furnished a few cases in which a similar occurrence took place.

The observations under a former head preclude the necessity of entering here upon the remittent form of yellow fever.

Sequelæ. — With the exception of a very few instances, we find that, in the records of yellow-fever epidemics, chronic organic affections have not been much referred to. Dr. Alfonso de Maria has recorded that, after a Cadiz epidemic, several who had passed through the disease were recommended to go to St. Lucar in consequence of the visceral diseases which followed; and Mr. Munro, in his official report of the disease as it occurred in the seventy-seventh regiment, at Falmouth, Jamaica, in 1827, states that "in cases of recovery from this form of the disease, the patient was generally a considerable time afterwards affected with some organic complaint, either of the lungs, liver, spleen, or other viscera." It may be a question how far some observations of Dr. Rush, regarding the Philadelphia yellow fever of 1794, apply to this point; that "the moderate degrees of it were of so chronic a nature as to continue for several weeks when left to themselves."

Diagnosis. — From what has been said, it must be evident that great difficulties stand in the way of affixing pathognomonic symptoms to yellow fever; it has even been observed, especially in regard to children, that those very slight attacks which occur not unfrequently during epidemics, and in which we have not a single well-marked symptom of fever, seem to give the *admitted degree* of immunity, during subsequent epidemics. As in some other diseases, we must rather point out those symptoms usually considered characteristic of an attack, than refer to any as invariably present. Nausea and vomiting, especially after the first twenty-four hours, are far more constantly present and more distressing than in any other form of fever; the quantity ejected is sometimes considerable, though nothing had for some time previous been taken into the stomach: and in this last case what is thrown up, until perhaps about the fatal termination of the disease, is usually colourless, as if simply a secretion from the stomach. Though, as is well ascertained, a black or dark-brown fluid is now and then vomited in other diseases, there can be no question of this symptom forming, at the fatal termination of cases, a very leading character in the great majority of yellow-fever epidemics. It is necessary to speak thus as to the *majority* of epidemics, for here, as in almost every thing else which can be mentioned respecting the disease, remarkable exceptions occur; as, for instance, in the 84th regiment at Jamaica, in the epidemic there of 1827, when, according to the surgeon's official report, the black vomit rarely appeared in the fatal cases: and at Gibraltar, in the epidemic

of 1814, when the same was observed there among the military. In young robust persons, the suffused and red appearance of the eyes is held to be among the common signs of the disease; but a much more unequivocal one is, in others more advanced in life, an intense redness of the adnata, but without any brilliancy, the natural secretions of the part being suppressed, and giving to the countenance rather a ferocious expression. The red, or, as it has been called by some, crimson border of the tongue, ranks among the most characteristic signs in the first stage of the malady. Jactitation is of more frequent occurrence, and more severe in degree than in any other disease, spasmodic cholera not excepted. In the forms in which the excitement runs high, the aching across the loins, of the calves of the legs, and of the eye-balls, is more severe than in any other form of fever. Though, on particular occasions in the West Indies, yellowness of the skin has been spoken of as being "as often absent as present," the propriety of considering this as a symptom to be looked for in the majority of cases is evident enough from the name given to the disease by so many writers of different countries. This yellowness may be partial or general, and may vary from the light lemon colour to deep ochre-yellow.* Hemorrhages from the different orifices must also have a prominent place. Suppression of urine is, in desperate cases, infinitely more common than in any other form of acute disease, spasmodic cholera perhaps excepted; and it is probably only in this last disease that we have, as frequently as in yellow fever, the acrid or "burning" sensation in the region of the stomach so peculiarly distressing. It has been attempted to set up, as diagnostic of yellow fever, an excruciating headach confined to the orbits and forehead, without extending to the temples, but the general application of this as a guide has been justly questioned.

Prognosis.—The following are among the unfavourable symptoms:—the *early* appearance of yellowness, especially a shade of it similar to what occurs in patches in ecchymosed parts; intense rachialgia; incessant vomiting and jactitation; deep sighing; intermissions or remarkable depression of the pulse; aching of the eye-balls; singultus, and, according to some observers, the appearance of a few drops of blood from the nose at a very early period of the disease. Opposed to some of these may be reckoned among the alarming signs, a feigned gaiety, or an assurance on the part of the patient that he suffers little, at a moment when a practised eye can discover cause for apprehension.

A fatal issue may be looked forward to when the patient, although in possession of his faculties, lies for the most part on his back, in a state of collapse; his limbs pulseless, clammy, and stricken with a degree of coldness considerably below that which is found to take place in a corpse under a similar atmospheric temperature; while probably he complains of agonizing internal heat, and casts off the bed-clothes incessantly. When, on the contrary, the patient lies on his side, completely enveloped in the bed-clothes, the temperature not remarkably reduced, labouring under no very striking symptom, indifferent to passing events, and annoyed at being disturbed, but answering questions rationally; in this case it is often supposed that the patient is enjoying a tranquil sleep: where the acrid sensation spoken of takes place, and which sometimes extends along the course of the œsophagus to the fauces:—when we have, as sometimes happens, from the very commencement of the attack, a knitting of the brows, a sort of scowling, *sinister* look, with the remarkable redness of the eyes, and what may be called a mottled or *party-coloured* skin, in which livid, light olive, and ash-coloured patches of all sizes may be observed shading into each other:—where a loud, monotonous wailing takes place, or a violent, sonorous, heaving of the chest, amounting to the degree of dyspnoea liable to occur from extensive organic lesions:—when lividity of the ears and hands takes place, or livid blotches or swellings on various parts, from the infiltration of venous blood into the cellular tissue:—when we have trismus, or slight spasmodic twitches about the mouth, or long-continued singultus:—when we have profound coma,* or the small whitish stools referred to, or suppression of urine, or, finally, black vomit. With regard to the occasional recovery of patients labouring under any of the foregoing symptoms, the statement in reference to black vomit is perhaps the most worthy of attention; the general impression being that it is *invariably* a fatal symptom. Dr. Rush, in his account of the Philadelphia epidemic of 1793, states that "many recovered who had this coffee-coloured matter."† Mr. Amiel, (now surgeon to the 12th regiment,) who has witnessed three yellow-fever epidemics at Gibraltar, states that he met with two instances in children where recovery took place after the appearance of black vomit. Surgeon Callow, of the 84th regiment, says, in his official report to the Army Medical Board, relative to the yellow fever as it appeared in his corps at Fort Augusta, Jamaica, in the year 1827, that the black vomit "is not invariably fatal; examples more than one in

* Regarding yellowness, it is quite inconceivable how any writer laying claims to the smallest knowledge of this disease could have placed a very light or lemon yellow as the true *diagnostic* colour; for nothing is better known than that the skin may assume a very intense yellow; so that the perspiration is even sometimes found to stain the sheets, as is remarked by Flores Moreno, and was observed in a few instances at Gibraltar in 1828.

* It seems strange that Dr. Boisseau, the erudite author of the "*Pyrétologie Physiologique*," should, in his last edition (1831), have given the integrity of the mental faculties as invariable in yellow fever; for, although he is a good deal borne out by the statements of Deveze and some others, it is nevertheless certain that in protracted forms the opposite is sometimes the case.

† Page 54.

my regiment are now living." He states that Captain Pack recovered eventually, "though he had a vomiting of coffee-coloured fluid for twelve hours." Dr. Bone, deputy inspector-general of hospitals, who has had an experience of many years in the West Indies, is very precise upon this point in an official report relative to an epidemic at Barbadoes in 1821. He there not only refers to some cases in which recovery took place after having vomited black ("China-ink coloured") fluid, as well as "flaky brown blood, usually the precursors of the real black vomit," but enters into minute details relative to two cases, ultimately terminating favourably, where the fluid ejected possessed the most unequivocal characters.

Recovery may be hoped for, even where hemorrhage the most profuse takes place from one or more of the natural orifices, if the number of patients be not so overwhelming as to prevent the possibility of allotting to those who are in such a state incessant care and good nursing. Reasonable hopes may be entertained, when, in the ordinary forms of the disease, the pulse is not found to give way remarkably about the end of the third day. Distinct remissions have been remarked as favourable. Surgeon Callow says, "if a distinct remission occurs, it generally proves a favourable indication." If the skin, during the first forty-eight hours, maintain an equable temperature and softness, there is great probability that symptoms of a very severe character will not set in. Serenity of countenance and a facility in moving the eyes are favourable

indications; but, with respect to the first of these, it is especially to be remarked that traits, often so light as to escape inexperienced observers, are of high moment; and on this account additional advice should be resorted to whenever practicable, even in what may seem a very mild case. The miliary eruption noticed by certain Spanish writers is to be regarded as favourable; so, in a high degree, are some hours of sleep not broken in upon by vomiting; and so are, as perhaps need scarcely be mentioned, dejections of a proper colour. The restoration of the moisture and bulk of the tongue from the remarkably dry and *withered* state often occurring in the protracted forms, is one of the most promising signs. Whatever be the colour of the urine, its secretion in due quantity is always a favourable point, though not to be considered as one of the most prominent indications of a favourable issue.

On the whole, the yellow fever is considered the most *insidious* of all fevers; for it is known that in persons sitting up in bed amusing themselves, and apparently in a favourable state, the black vomit has suddenly appeared, quickly followed by death, to the utter astonishment of the medical attendants.

Morbid appearances.—1. In cases of *extreme malignity, and terminating rapidly (concentrated form,—congestive form)*. The party-coloured appearance remarked as existing during the attack in this form, more strongly marked, the lividity being more prominent, especially in the most dependent parts; and a pale yellow line, mingling with the other colours, can be observed from about the nose to the pubis. The ears, hands, and arms quickly become of a brown-black; the palms being equally dark with the backs of the hands. The penis and scrotum also become particularly dark. This appearance of the body has sometimes given rise to a hasty conclusion that rapid decomposition had taken place; but it does not appear, from observations made during a long time in dissecting rooms, that the odour of putrefaction takes place sooner after death from yellow fever than in other cases. *Cellular tissue*, unhealthy in appearance, but having no yellow tinge. *Muscles*, dusky, and softer than natural; so that they may usually be broken down by pressure between the fingers. *The heart*, same appearance as other muscles. *Liver*, change of colour seldom very remarkable; but light olive patches are sometimes observable, which would seem to indicate that a change similar to what is common in the more protracted forms of the disease had commenced in this viscus. No trace of inflammation, by adhesions, abscesses, &c. Congestion, though not always present in a remarkable degree, has been observed. *The gall-bladder*, remarkably diminished in size, (sometimes shrunk, and in other instances greatly attenuated); altogether empty, or only containing a *minute* quantity of bile of a deep orange-red colour, or of green bile, or of serum, or, more rarely, of pus; its mucous lining in some instances highly injected with blood of a bright red

* Dr. Bone, who seems to have paid much attention to the examination of the fluids ejected from the stomachs of persons labouring under yellow fever, describes them thus:—"1st. The contents of the stomach at the invasion of the disease. 2d. The fluid drank, mixed with green or yellow bile. 3d. The fluids drank, without any admixture or change. 4th. A fluid like indigo or China ink, brought up with some straining: I suppose it to be bile, for it coagulates with spirits of wine. 5th. A brown fluid, resembling urine in appearance. 6th. Brownish blood, not flaky, proceeding from the fauces and gums, and perhaps partly in some cases from the pulpy cardiac opening of the stomach. 7th. Brown flaky blood, mixed with mucous matter, proceeding from the gums, fauces, and stomach, usually the precursor of the real black vomit. 8th. *The real black vomit*, which also is blood altered by its passage through the vessels of the villous coat." At Gibraltar, in 1828, we were led to consider "*black vomit*" under the following forms:—1st. In thin flakes or portions of a brownish black colour, floating, like broken-up wings of a butterfly, in a glairy fluid, or in a fluid resembling an infusion of black tea. 2d. A perfect resemblance to a mixture of soot and water, or to the contents of a coffee-pot when the clear part of the coffee has been poured off. 3d. A homogeneous, intensely black substance, having a jelly-like consistence, and adhering in great abundance sometimes to the mucous coat: this, though never vomited up, and therefore more properly belonging to the *morbid appearances*, it is thought may not be altogether out of place here:—it is rarely found in the stomach, the intestines being much more commonly its seat. A simple test of true *black vomit* has been proposed, which is dipping into it white paper, which it does not tinge.

colour.* *The cystic duct*, in a few instances so completely closed that a probe could not be passed through it.† *Peritoneal surface*, free from adhesions or other evidence of inflammation. *Stomach*, free from what, in the present day, is admitted by the best authorities to be evidence of inflammation; mere redness, whether in streaks in various directions, or in stellated patches of various sizes, has been on several occasions remarked in the mucous membrane, in the same degree as it is observed to occur in chronic or other diseases, or in cases of accidental death, where there is not the remotest suspicion of gastritis. Spots of a purple colour are much more common than those of a bright red. A perfectly pale state of the membrane is far from being of rare occurrence. Dark streaks or patches in the mucous membrane are not uncommon, and would give an impression of their being occasioned by blood, changed in the capillaries to *black vomit* in its progress to the surface. This appearance no doubt it is which has given rise to the opinion that gangrene of the stomach occurs in yellow fever; but the most careful examinations at Gibraltar, in 1828, fully bear out those observers in America, the West Indies, and Spain, who deny not only that gangrene does take place in the disease under consideration, but also that any lesion whatever of the stomach is to be traced. As the same may be said, very confidently, with respect to the other parts of the body, it would be unprofitable to enter more into details upon this part of the subject; and it need only be observed further that here the contraction of the bladder has appeared to be constant.

2. *Where death takes place after the more ordinary forms of the disease.*—Little lividity of the skin, except in dependent parts. Where no yellowness has appeared during life, a little may now be observed about the eyes, at the sides of the nose and mouth, along the course of the large vessels of the neck, and about the chest. Where yellowness had existed during the attack, it now becomes more intense and general, and extends to the fat and cellular tissue; but it is proper to state that the assertion as to the pericardiac fluid and that contained within the ventricles of the brain being sometimes tinged yellow, has not been verified under the observation of many who have had ample experience in this disease. *Muscles*, their natural colour and firmness little altered. *Peritoneal surface*, free from adhesions or other evidence of inflammation. *Liver*, presenting remarkable changes of colour. Sometimes (as during the greater part of the Gibraltar epidemic of 1828) the colour has been a pale

olive, or mixture of green and yellow, usually taking place uniformly throughout the whole substance of the organ, in some rare instances alternating with dark green, in regular strata, and occasionally taking place in the left lobe only; the liver observed, at the same time, to be studded, or punctuated, very thickly, with minute spots of bright red, being, perhaps, the granulated structure retaining its colour. The colour of the liver is, in some cases, especially in women and children, lighter than here described. In children it has been observed, after having been merely put into water for a moment, to be as pale as box-wood. Another change of colour is to reddish brown, compared by some (Arejula, &c.) to that of red Peruvian bark, and by others to the leaves of an autumnal scene: this was almost the only change of colour which presented itself during the latter part of the epidemic season of 1828 at Gibraltar. Portions of the liver washed, pressed, or bruised in a mortar, did not give out colouring matter, whatever the shade might have been; and portions of the light olive coloured have remained unchanged by long immersion in spirits of wine. Little or no blood exuded from this viscus when deep incisions were made; and when broken up between the fingers, the impression given was what is termed *friability* of texture. No trace of bile has been observed in the pores on the occasion just referred to, nor had the hepatic or common duct been ever found obstructed, like the cystic; no traces of inflammation discoverable, and from the whole of what has appeared upon this subject, the morbid change may be considered as being connected with derangement of *function*. The *gall-bladder*, usually containing bile, of a highly inspissated and sometimes dark tar-like appearance. *Stomach*, not unfrequently found to contain the *black-vomit* strictly so called, and, though infinitely more rarely, may be smeared over with the dark adhesive and jelly-like substance spoken of under another head; containing sometimes an obvious proportion of blood mixed with other fluids; often the ingesta only, or mucus. Ruge, the "*état mamelonné*," together with appearances adverted to under another head, as they are admitted to present themselves very frequently in dissections after diseases of any kind, or, indeed, where (as in the case of accidental death) no disease had existed, need not be particularly entered upon on this occasion. Those who have asserted that ulceration of the stomach takes place in any form of yellow fever, are quite unsupported in the statement by observations made with the greatest attention and on a scale of sufficient extent: that mistakes have here, as on other occasions, often arisen from the facility with which the mucous membrane gives way on handling, there seems little reason to doubt. As to mere "*ramollissement*" of this membrane furnishing a proof of inflammation, this will not be now contended for, it is presumed; and it may be here stated that, on an examination in the case of a death by accident at Gibraltar in 1829,

* It is to be remembered that, though these appearances were so constant in the examinations made on an extensive scale at Gibraltar in 1828, they have also been occasionally found by pathologists in other fevers, and even in phthisis.

† This, as is well known, occurs in other diseases: if the peculiar valvular as well as spiral structure of the duct be not kept in view, we shall often be misled in supposing that actual occlusion exists.

where the man had been in perfect health previously, the whole of this membrane, in the intestines as well as stomach, was, in the hands of experienced persons from Paris, found to be so soft that, with the utmost care, not more than two or three lines of it could be raised at any point, but for the most part not even that quantity. The *œsophagus* presents an appearance, in some of the cases where *black-vomit* takes place, of this being thrown out from its surface as well as from that of the stomach, especially at its lower portion; an abrasion of its epithelion throughout its whole course has been sometimes observed, as in examinations after other diseases. The idea suggested itself at Gibraltar that this denuded state of the tube might give rise to the peculiar burning sensation noticed; but as the same sensation has been observed to occur frequently in cholera, a wider field is open on the point.

Duodenum, much of what has been observed regarding the stomach will apply here. *Small intestines*,—even in cases where no black vomit had been ejected before death, or where, on inspection after death, it had not been found either in the stomach or duodenum, the black jelly-like substance was sometimes found in the jejunum, but oftener in the ileum; and in some cases where it has been found both in the stomach and ileum, the whole intervening jejunum has not presented a trace of it. In a memoir by the writer of this article, from which imperfect extracts were some time ago printed in Paris, the remarkable fact was noticed that the ulcerations so liable to take place during the progress of typhus, as well as other fevers *malæ moris*, in that part of the ileum more especially occupied by the glands of Peyer, are not found to take place in yellow fever. The most trifling lesion has not been discovered in those parts of the intestine, on very careful examinations. The *colon*, its mucous surface sometimes covered with the adhesive black substance; in a few instances containing a quantity of a pale red fluid, approaching to blood in its character; is occasionally contracted at different parts. Whether we speak of the stomach or intestines, the mucous surface is usually found quite pale on removal of the particular substance described as being black and jelly-like. In the colon especially, but also in the small intestines, another substance has been occasionally found adhering in great quantity to the mucous surface; this has been compared by French writers to a mixture of linseed-meal and water; but it has been found of a lighter colour, so as to resemble the substance found sometimes adhering to the intestines of persons who have died of cholera spasmodica. Regarding red points or patches found not unfrequently in different parts of the intestinal canal, little need be added to what has been said, when speaking of the mucous membrane of the stomach, as to their not furnishing evidence of inflammation. If, as is the opinion of some of the most eminent pathologists of Europe, before inflammation

of this surface be admitted it must be shewn to be thickened as well as being red and so soft as not to admit of being torn off in portions of several lines in length, then may it, as we conceive, be with much certainty stated that the phenomena of yellow fever cannot, as has been supposed, be referred to *gastritis*, or *gastro-enteritis*. The *bladder*, in those cases where suppression of urine* took place, found contracted very remarkably, but without lesion. Mr. Linton, of the Naval Hospital, Jamaica, has noticed in one of his official reports, that he considered “the *pancreas* in some cases as being friable in texture;” but this has not been remarked by others who have paid the closest attention in their examinations; and regarding the alterations or lesions alleged from time to time to have been observed in other parts contained within the abdominal cavity, they do not seem to be verified in subsequent examinations conducted on a larger scale.

Within the cavity of the thorax no appreciable lesion of organs seems to be admitted in the more ordinary forms of yellow fever; the change of colour and friable texture of the heart, in the highly concentrated form, has been referred to. False polypi in the cavities of the heart have perhaps been more common in this form of yellow fever than is usually found to be the case after death from other diseases. In a limited number of cases, towards the close of the epidemic of 1828 at Gibraltar, the attention of the medical officers of the garrison was directed by some of the members of the French medical commission to those dark, well-defined, circular patches in the lungs, having very much the colour and consistence of the spleen, which have been noticed in other diseases, and the appearance of which was perhaps merely adventitious on the occasion in question. In the examinations made in the year just mentioned, the blood was not observed of the particularly dark colour attributed to it in this disease by a few writers. The question, however, as to the changes in the chemical properties of this fluid remains open. *Contents of the cranium*: In the course of the last Gibraltar epidemic, as well as on other occasions in the West Indies and elsewhere, extensive observations, carefully conducted, have quite negated any assertions made from time to time as to morbid changes in the substance of the brain; as an inordinate quantity of fluid in its cavities, or under its coverings; remarkable congestions; extravasation of blood; the effusion of lymph, &c.: even where profound coma had taken place in the Gibraltar cases, morbid states by which this might be explained were not discovered; and the deviations from perfectly natural states observed in any cases, were considered, by those who had most opportunities of making the examina-

* In some cases, especially children, retention of urine has taken place in this disease and been mistaken for suppression; so that, on a post-mortem examination, the bladder has been found distended above the pubis: the occurrence of this at Gibraltar in 1828 led to the practice of careful examination of the region of the bladder.

tions, as nothing more than the fortuitous appearances which present themselves in a proportion of instances, no matter from what disease death is produced, and which, as is now generally admitted, may arise from stasis, or the longer duration of the last agonies in particular instances: cadaveric changes, too, have, no doubt, given rise to mistakes, particularly as to great vascularity or congestion in the posterior and more dependent parts of the membranes of the brain, as it has regarding the most dependent folds of the intestines. *Contents of the vertebral column*, found to be equally free from lesion as those of the cranium. In examinations conducted on a small scale by a French medical commission sent to Barcelona during the epidemic of 1821, erroneous views had been hastily adopted as to the spine being the *fons et origo mali* in yellow fever; but those opinions were, wholly or in part, subsequently admitted to have been erroneous. Magendie having shewn that a certain quantity of fluid within the theca belongs to a natural state of the parts, errors on the part of future observers are less likely to occur.

Before quitting the subject of morbid appearances, it may be stated that a very remarkable occurrence presented itself in a few instances during the last Gibraltar epidemic,—the infiltration of venous blood, in the most uniform manner possible, into the cellular tissue of the minutest fibres of muscles. The whole substance of the muscles, which appeared almost black, seemed one soft mass, which yielded to pressure between the fingers as readily as the spleen. The blood thrown out became grumous, so that incisions caused but little exudation from the parts; no putrid odour or appearance of sloughing. In one man this infiltration took place into the whole of the muscles of the right thigh, the abductors excepted, from their origin to their insertion; in another the parts involved were the gastrocnemii of the left leg and flexors of the right arm. This man had suffered a good deal of pain in those parts, and the process was very rapid. In a third case precisely half the diaphragm (right side) was found in this state; and the infiltration, bound down by all the foldings of the peritoneum, extended in a most singular manner in one continuous sheet, from the diaphragm, posteriorly, down the right side to the bottom of the pelvis, keeping with great precision a line corresponding to the axis of the vertebral column, and covering every organ, or part of intestine, &c., which lay on that side. The muscles, except in the portion of the diaphragm referred to, were healthy. In this case the disease had run a rapid course, and some of the symptoms were well marked, as yellowness of the eyes and skin, violent jactitation, delirium, singultus, and dark stools, but no black vomit: a remarkable tremulous motion of the hands, not common during the epidemic, also took place in this case, near the close of the attack. We were not in those cases able to discover the rupture of any considerable vein.* Although Arejula notices in his work the occurrence of

large and painful tumours during some of the epidemics of Spain, which, had examinations after death taken place, would probably have been found of the nature just referred to, nothing as to the occurrence, in the yellow fever of parts of Europe, of the precise morbid states here referred to appeared till the publication, at Paris, in one of the numbers for 1829 of the Bulletin of Sciences, of an abridgement of notes, made by the writer of this, of the autopsies at Gibraltar, in 1828. Up to so late a period as 1828, the identity of the yellow fever of Spain with that of the West Indies had been denied by Dr. Rocheaux, who was at Barcelona in the epidemic season of 1821; but the editors of the Bulletin consider all doubt now at an end, "*identité parfaite*" being established by the account of those infiltrations in the cellular tissue in some of the Gibraltar cases. In America and the West Indies those appearances had been particularly noticed by Dr. Chervin of Paris, so celebrated for his researches in yellow fever for many years; they are particularly noticed in a communication to the Academy of Medicine, in 1827, by Dr. Keraudren, from one of the French West-India islands.

Mortality.—As has been frequently observed regarding other diseases, the malignity of the cases, and consequently the mortality, is usually much greater in the first than in subsequent periods of yellow-fever epidemics: the violence of the disease has, however, been known to receive, in some rare instances, a fresh impulse, as at New-York in 1822.* In *Hurtado's Decadas* it is stated that, of the first 134 cases treated at Murcia in 1804, not more than three or four recovered. Dr. Rocheaux, one of the French physicians at Barcelona during the epidemic of 1821, states, in his book on yellow fever, printed in 1823, that in the early part of the epidemic the mortality was in the proportion of 19 out of 20; that towards the middle it became much less, and at the close was only two-thirds.† In the early part of the Gibraltar epidemic of 1828, very few recoveries took place in the Civil Hospital; of the first thirty-five Jews received into the establishment, it is stated that all but one were swept away. On the same occasion, two corps in particular, as officially stated to the authorities by the late Dr. Hennen, then medical chief, were early attacked by the disease in a peculiarly malignant form, and suffered a loss of about one-half of the cases. On some occasions the form of the disease has been so mild that very few deaths have been recorded in proportion to the numbers attacked: even during the same epidemic, from a difference in the localities, or from other circumstances not admitting of easy explanation, there has been less mortality, in proportion, in one regiment,‡ class of persons,

* About the middle of October "the disease became again as fatal, or indeed more so, than at its commencement; the proportion of deaths being to the proportion of sick as three to four!"—*Townsend, Yellow Fever of 1822 at New-York*, p. 197.

† Vide p. 464.

‡ At Gibraltar, in the epidemic of 1813, the mor-

or family, without an essential difference in the mode of treatment, and solely arising from the disease having been milder. A full consideration of the subject must prove that the *expectante* system, or any system of "mild popular remedies," cannot be admitted (as has been attempted to be shewn) to be followed by less mortality than what our French neighbours call "*les moyens perturbateurs*." It does not appear that in their colonies, where trifling means only have been so often resorted to by the French, any good has followed. At Barcelona, in 1821, scarcely a patient survived in the wards given up to the distinguished members of the French commission.* At the period in question, the mortality, under Spanish and French medical men, in the establishment called *Seminario*, was 1265, out of 1739 cases treated. Under the *mild*, or what has been called the French and Spanish treatment, the mortality at Malaga in 1804 was 11,486, out of a population of 36,054. In the epidemic of the preceding year at the same place, 6,684 deaths occurred out of 16,517 attacked. In an epidemic at Xeres a few years ago, one-third of the whole population was swept off, under circumstances when, in the bulk of the patients, a few domestic remedies only could have been employed. Many other similar instances might be cited in proof of our being warranted in employing potent means likely to induce a favourable change in the form of the disease on its first invasion. From the wide range which the symptoms take,—so wide that, but for the *black vomit* being *liable* to occur, as a connecting link in the various forms during the prevalence of an epidemic, we should, from the symptoms, as well as *post-mortem* appearances, often have reason to suppose that different remote causes were giving rise to different impressions,—it is obvious that in no disease is it more difficult to lay down rules of practice, and in none can the medical man's tact and attention be more needed.

Nature of the disease.—It has been attempted, on various occasions, to explain the phenomena of the disease by the inflammation of certain organs or parts; and by the majority of those who have adopted this view of the matter, the gastro-intestinal mucous membrane is the part to which the morbid action has been assigned.† As might have been anticipated, we find this doctrine supported by all the ingenuity of Broussais and his followers; but by nobody has it been more strenuously advocated than by M. Boisseau, in his "*Pyrétologie*."‡ Among the medical men out of Europe who have advocated this last opinion, the statements of Dr. Bone, of the British army, who has been resident for many years in the West Indies, are

perhaps worthy of most attention: they are to be found among the many valuable manuscript documents in the archives of the Army Medical Department in London. What has been shewn, however, under the head of *morbid appearances*, will probably establish, to the satisfaction of our readers, that there are sufficient grounds for believing that the primary morbid action is not the alleged inflammation of parts. The inhalation of a specific poison has, as on other occasions, been considered by some as directly productive of changes in the chemical properties of the blood sufficient to account for the derangement of various functions which occur in this disease; but, without denying the probability of this, there is as yet nothing before the public to establish the point satisfactorily. Dr. Guyon, who practised for some years at Martinique, has spoken of this "*lésion*" of the blood as probable; and Dr. de Fernon of Paris, well known for his acumen in all matters relating to medical science, seems to favour this view of an alteration of the blood, '*primitivement*,' in yellow fever. In the most concentrated and rapidly fatal form of the disease, there is evidence, as has been shewn, in proof of congestion in the liver. By others, the nervous system is considered as primarily affected, and some observations lately made on this subject by Dr. Wilson of the navy, in his very ingenious book on yellow fever, seem particularly worthy of notice; especially with respect to the different train of symptoms to be looked for—on the one hand by the *abstraction*, and, on the other, by the *obstruction* of the nervous power in different individuals. The uniform integrity of the cerebral functions in the first stages of this malady, as observed at Gibraltar in 1828, and as noticed on other occasions by many authors—the extremely frequent integrity of those functions to almost the last moment of existence, in its '*congestive*' or most intense and fearful form,—together with the remarkable manner in which (in the last-mentioned form especially) the secretions are suspended,—induced the writer of this, when drawing up a review of the last Gibraltar epidemic (1828), to state his belief that the ganglionic system was involved, *very prominently*, in the series of morbid actions. That this should in any case be the first link of the chain can never perhaps be satisfactorily demonstrated; but on many occasions it appears highly probable from the manner in which several fatal signs concur with the suppression of the secretions, as if some powerful agent had been directly applied to that system of nerves which so specially presides over the secreting organs. But to enlarge on points necessarily speculative would be unfitting an occasion like the present.

Cause of the disease.—The more fully this subject is examined, the more evident it must appear that in the present state of our knowledge nothing satisfactory can be arrived at; for although, as will be shewn when speaking of *contagion*, reasonable causes have been sometimes assigned for the appearance of the disease on board ship as well as in certain localities, it

talities was so much less in the Military Hospital under Mr. Brown, that medical gentlemen were induced to inquire into his practice, which they found did not differ from their own.

* O'Halloran on the yellow fever of Spain.

† Tomassini, strangely enough, considers not only the gastro-intestinal mucous membrane as the seat of inflammation in yellow fever, but also the liver.

‡ Fourth edition.

has been impossible to assign appreciable causes in many other instances. What can be stated in this respect with regard to Gibraltar, will apply to other places. By ample tables in our possession, it does not appear that either before the appearance of the epidemic of 1828 in that garrison, or during its progress, any atmospheric changes took place differing materially from other years in which epidemics did not occur. The average heat was not greater* than that of the preceding year. The quantity of rain which had fallen up to the appearance of the epidemic was within a fraction of that which fell in 1827. The influence of a prevalent easterly wind had been much dwelt upon in the explanations offered respecting the epidemic at that place in 1804; but in 1828 no unusual prevalence of that wind took place. In fairness, we think that, like many other places which may be mentioned where yellow fever is known from time to time to appear, it cannot be admitted that Gibraltar furnishes sources from which *malaria*, in the usual sense of that word, arises, sufficient to account for the appearance of a malignant fever; neither can we concede to authorities of great respectability, that either there or in various other places the solution of the question is to be found in a crowded population, the filth of the town, or the state of the sewers; though the last may have been an auxiliary. Compared with Gibraltar, places might be mentioned where, as we know, yellow fever does not appear, in which those circumstances obtain in a much greater degree. It may be urged against the salubrity of Gibraltar, that the habitations are for the most part deprived of free ventilation, being backed by a rock of from twelve to fourteen hundred feet high; and that the impinging of the sun's rays, for so many hours daily, on the sloping and inhabited part of the rock, should be admitted to a share in the consideration: but the great mystery is, that with these and other circumstances in operation every year, the disease should only prevail epidemically in particular years. Though a certain degree of heat seems so essential, it by no means appears that epidemics have usually occurred in years most remarkable for heat. If we consider soil and elevation, it must be admitted that here too no satisfactory conclusion can be drawn; for if we find evidence, especially in the West Indies and on the American continent, of the influence of a marshy soil, on several occasions, this does not hold good in other instances; and in those countries, as well as in Spain, many places might be mentioned where elevation, soil, &c. would seem to guarantee immunity, but where, nevertheless, the disease occasionally prevails to a devastating extent.

Notwithstanding what has been here said, we do not apprehend that, in the present day, epidemic or catastatic influences in determining the irruption of diseases will be denied, though

not cognizable by our senses, or appreciable perhaps by chemical tests.

Influence of temperature, &c.—There is nothing connected with yellow fever which seems so invariable as the decline of the epidemic on the setting in of cool weather. At a temperature of about 50° Fahr., fresh cases soon cease to appear, and in Spain and North America the disappearance of the disease at a particular period is usually calculated upon with precision.

In some epidemics females have remained wonderfully exempt: this was the case during a terrific epidemic at Dominique and Martinique in 1801, as the writer of this witnessed; for while two battalions of the 68th regiment, composed of fine young men, suffered so much from the disease as not to be able latterly to furnish any men for duty, and had lost forty-six officers within six months, not a single woman was attacked; and it may be observed that, in those days, more females were allowed to embark with regiments from home than at present. Children were also exempt on the occasion in question. In some epidemics in Spain the disease has been observed to attack women in a milder form; while in others, as that of Xeres in 1811, they suffered in a particular manner. During the early part of the epidemic at Gibraltar in 1828, the women were attacked with great severity, but subsequently in a milder form. On that occasion, too, children under twelve months had well-marked symptoms.

Particular classes will sometimes suffer more than others; thus, according to a memoir by Mr. Hugh Fraser, lately surgeon to the Gibraltar Civil Hospital, of the first thirty-five Jews who presented themselves to him during the epidemic there of 1828, scarcely a single person recovered. Bakers and cooks have been said to suffer in a greater proportion than common; but perhaps the nature of their occupations permits fewer of these people, in proportion, from leaving a city or town when an epidemic prevails. Negroes are considered as being usually insusceptible of attacks; but even in them a susceptibility has been created, as on certain occasions in America, by a residence for some time in a different climate from that to which they had been long accustomed: indeed, without change of climate, they have, as instanced by Dr. O'Halloran in his report of the Jamaica epidemic of 1825-6, been attacked in considerable numbers, though not with equal severity as the white population. At Gibraltar in 1828, a negro, the servant of a hotel-keeper, had two attacks, one of which was particularly well marked. Circumstances connected with localities being equal, the upper classes of society seem, on all occasions, to suffer from attacks in a full proportion. Persons of regular habits do not seem less exempt from attacks during epidemics; but it may be admitted that their chance of recovery is greater than in the case of free livers. Those born or long resident in places where the disease is liable to prevail, will escape from attacks during the prevalence of some epidemics, while in others

* Average at noon, in the autumnal quarter, 76½
in the last quarter, 63½

(as in that at Barbadoes in 1816, and Jamaica in 1825-6) the old inhabitants will suffer in proportion. A well-marked attack on one occasion gives a great degree of security from attacks during subsequent epidemics: this was stated, some fifty years ago, by Lining, reiterated by Sauvages, and known so well among Spanish medical men, that the late Dr. Arejula placarded the fact on the corners of the streets in Medina Sidonia in 1801, with the view of insuring better attendance to the sick: the claims, therefore, of some persons of late years to any *discovery* on this point, are utterly groundless, as are the statements which would go to the denial of the fact, regarding the occasional occurrence of two distinct attacks at remote periods; and, were this a place for minute details upon every point connected with yellow fever, a list could be furnished of the names and dates of several which took place at Gibraltar. Relapses are very common: at Gibraltar, in 1828, one hundred and two cases of relapse occurred among the military alone; and their names have been registered in the medical office of that place. The occupiers of upper floors have, in many instances, especially at the commencement of epidemics, been attacked in fewer numbers than those on ground floors; and in the West Indies and Gibraltar, families occupying low huts have frequently furnished the first cases. The manner in which the disease has sometimes been confined to a particular extremity of a building, or even to a particular side of a ship, is well illustrated by surgeon Callow, 84th regiment, at Fort Augusta, Jamaica, in his official report for 1827; and by surgeon Wilson, Royal Navy, in his work on yellow fever.

Treatment.—It is painful to be obliged to admit that our advancement, within the last half century, towards any thing like a satisfactory treatment of this disease, in its formidable shape, has been sadly disproportionate to the degree of intellect brought to bear upon the subject within that time by professional men of different countries. Even with respect to those forms in which the symptoms, though formidable, are comparatively less intense, it seems very difficult to draw, from a review of what has been done by many, fixed rules for our guidance on certain points of practice. The discrepancy in the statements of respectable authorities regarding the efficacy of a particular line of practice can indeed be no otherwise explained than by the admission that in some epidemics very remarkable peculiarities occur.

Venesection may be particularly referred to in illustration; for though it has over and over again, after trials in the hands of men who are not to be set down as injudicious, been decried in our West India colonies as well as America; and though it has been generally abandoned long since by the experienced practitioners of Spain, we find it, nevertheless, lauded on certain occasions, especially very lately at Trinidad, jointly with the warm bath and other means, by persons of unquestionable judgment. On our first acquaintance with this disease, nothing would seem more plainly in-

dicated than this remedy, when the excitement runs high; but it has been too frequently found that after its employment, even but to a limited extent, the true character of the disease had been masked, and, as the Spanish practitioners express it, that the patient is speedily found to require all the strength which had been *taken away*. Frequently as we have witnessed blood taken from the arm in this disease, under a strong impression that a highly inflammatory action was going on, never has the blood, in a single instance, presented a buffy surface with a firm coagulum; it has on the contrary always formed a loose mass, yielding readily to the pressure of a finger, the serum separating very imperfectly or not at all. It may here be mentioned that our experience by no means bears out the assertion of some, as to the remarkably dark colour of the blood drawn from yellow fever patients. Without any intention to impugn the statements respecting the advantages derived from liberal venesection on particular occasions in the West Indies, it must be declared that the weight of evidence is against its general adoption in yellow fever, even where, *prima facie*, it would seem to be indicated. The valuable naval medical records at Somerset-house being rendered accessible for reference by the liberality of Sir W. Burnett, some highly interesting observations on the point in question will be found in the reports from Mr. Linton, who has been long resident in the West Indies, and for some time in charge of the Naval Hospital at Jamaica. Quite in accordance with our ample experience of the disease, as it has appeared in the West Indies and Gibraltar, this gentleman declares the disease as “decidedly not inflammatory,” though “inflammatory symptoms may concurrently or adventitiously take place;”—would adopt the expression “*inflammatio simulata*,” as expressive of “irritation or vascular sensibility:”—states that in the records, extending back for many years, the mortality was very great from the depleting system, which, from the *seeming* inflammatory nature of the disease, had been acted upon; and that “the *post-mortem* examinations which have occurred within the last twelve months [referring to a particular sickly season] presented no appearances which could be legitimately ascribed to this state [inflammation].” As in other fevers, circumstances will arise where the application of leeches to the temples, or of leeches and cupping-glasses to the epigastrium, may be strongly indicated; but the experience of others bears out the last-quoted gentleman in a remark that there is great risk of mischief from opening the temporal artery, collapse being very liable to be induced. Having mentioned cupping, it suggests itself (though perhaps not as a very promising speculation) that in the hope of affording some palliation of the incessant vomiting often so very distressing in yellow fever, we may give a trial to dry cupping on the epigastrium, as practised by ancient physicians in their endeavours to relieve the vomiting in malignant cholera. *Blisters*, with this object, are fre-

quently applied at an early stage to the same part; but to Mr. Linton of the Royal Navy the profession is indebted for a suggestion as to their application in another manner with the same view. He states in a report from Jamaica, dated September 1830, that having placed a blister the whole length of the spine in a certain number of cases, the irritability of the stomach was relieved in all except one. Their application to the head is sometimes found beneficial in protracted cases accompanied by cerebral affection. The *warm bath*, where we have not morbid heat of surface with high vascular action, holds its place as a useful auxiliary in the early stage; and where these symptoms predominate, the *tepid bath*, occasionally repeated, is employed by many; or, by some, the *cold bath*, or sponging with cold water, or with vinegar and water. Assiduous friction of the whole surface, after the bath in any form, has been considered beneficial. The promised advantages from Dr. Jackson's suggestion of a cold bath with frictions, immediately after a warm bath, have not been realized. The application of cold by means of wet cloths to the forehead has been found useful in relieving the severe frontal pains liable to occur in persons in the full vigour of life.

Regarding *internal remedies*, they cannot in truth be spoken of in this as in almost all other diseases, for in the generality of cases the irritability of the stomach is so great that hour after hour, at the period when medicines might be hoped to make some impression on the disease, drinks of the mildest kind and medicines of every description, even in the smallest quantity, are instantly rejected; and, driven to total despair of anything being retained, we are often obliged to leave nature to her own resources, in the expectation of an interval of repose. In a disease of this kind it seems quite impossible to explain how, up to the time of his death, large doses of the *bark* should have merited the special favour of Dr. Lafuente, one of the principal physicians connected with the epidemics of Andalusia during some of the first years of the present century. Where remissions take place, as noticed by several authors, as well during convalescence, the advantages from the exhibition of *quinine* seem to be generally admitted; but the doses must be regulated with caution, for given in large quantities, it has not only produced great irritability of the stomach, but much mischief in the head. Among a very limited number of practitioners have *emetics* been at any time in favour. Arejula, the great authority on the epidemics of Andalusia, informs us that in pregnant women he found their exhibition prevent abortion and its usual consequence, death: this, to the extent of a few cases, seemed to have been corroborated in the practice of a Spanish medical man at Gibraltar, in the epidemic there of 1828. In a report drawn up by a commission of Seville physicians, relative to an epidemic which prevailed in the quarter of Santa Cruz, in that city, in 1819, it is stated that much reliance had been placed on the exhibition of antimonial emetics

in the early stage.* In No. 16 of the *Gazette of Health*, there is a paper by Dr. Hacket, surgeon to the forces, in which, referring to a late period of sickness at Trinidad, he states that his "practice commenced in almost every case by an emetic of sulphate of zinc;" and it would seem that in the employment of this, in addition to his other means, he found sufficient reason for being satisfied as to its utility. This may be the place to refer to the exhibition of the nitrate of silver, given by Dr. O'Halloran, surgeon to the 77th regiment, at Jamaica, in 1827, in doses of from four to six grains, so as to act as an emetic; and from which this gentleman at one time conceived that he had received considerable advantages in his practice; but it is proper to state that, however further trials of this particular form of medicine may be warranted, he has not, in a conversation which we have had lately with him on the subject, expressed himself very confidently as to its efficacy. In regard to *purgative medicines*, there seems, among the mass of experienced practitioners, an admission as to the propriety of their employment in those forms where the excitement runs high, although the practice is not without opponents from the modern school, which refers the train of symptoms in this as in so many other diseases to inflammation of the gastro-intestinal mucous membrane. It is not an easy matter to conceive how, in this disease, bulky doses of drastic purgatives, as jalap, &c. could have merited the estimation in which they were at one time held, their immediate rejection from the stomach being always so exceedingly probable. This unquiet state of the stomach has led to a very general practice, especially (but by no means exclusively) among British medical men, of administering, in as small a form as possible, doses of calomel with the view of clearing out the bowels as a first step; and whether in the form of small pills, or the powder in half a teaspoonful or so of gruel cautiously swallowed, there is always a greater chance of its being retained than perhaps any other form of purgative. It would seem, however, that the proposed object may with more certainty be obtained by the application of the croton oil to the tongue, as particularly recommended in the number for August, 1825, of the *Medical and Physical Journal*, by Mr. Tegart, formerly chief of the medical department of our West India islands. A drop or two on the tongue has not only excited the immediate action of the bowels, without increasing the irritability of the stomach, but has also been observed to favour the secretion from the kidneys, a point perhaps of no small importance. In the paper by Mr. Hacket, which has been referred to, written this year (1832), no small share of success in the treatment of the yellow fever at Trinidad is attributed to the croton oil, which it would appear this gentleman gave in large doses, as well as exhibiting it in the form of enemata; for after mentioning the emetics of sulphate of zinc, bleeding in the warm bath, the shower bath, and enemata

* *Decadas de Hurtado*, vol. iii. p. 120.

of salts and castor oil, where there was much excitement, he states that "croton oil was invariably given to the extent of three or four drops. I have known this repeated thrice through the night; and it is most worthy of remark, the more irritable and distressed the stomach,—though, *primâ facie*, to those unacquainted with the great febrifuge virtues and extraordinary powers of croton oil in restoring the peristaltic motion of the intestines, which seems in other diseases to be inverted altogether, this irritability, hitherto our bane, (I may almost say the very leading feature and peculiarity of tropical fevers,) would be to them a cogent reason for not administering the oil—yet in almost all such cases it was found invariably to be triumphant, so that in the morning we generally found our patient thus treated with a perfect or nearly perfect remission." He says, a little further on, "the power of croton oil in allaying gastric irritability and general nervous excitement, as well as restoring the circulation to the surface, and thus relieving the congestive state of the internal and deep-seated central vessels, is really extraordinary; and though it may seem for the moment, when first given, to increase that irritability, yet after a little time I have hardly ever seen it fail in producing the desired end." Much as we are taught by experience not to be too confident in our expectations of the efficacy of medicines, from the advantages which may seem to result from their employment in particular instances, there is enough here, from a gentleman who has had ample field of observation, to draw special attention. According to an official report referring to the events of the epidemic of 1821 at Barbadoes, Dr. Bone, deputy inspector-general of hospitals, who had a very important charge at the time, relied chiefly on the exhibition of opening medicines of the saline class; during the first twenty-four hours, for instance, four ounces of Rochelle salts, with or without two grains of tartarised antimony, given in small doses. But if what he considers as obstruction of the gall-duct took place (shown by the absence of bile from the dejections), he continued this solution, with perhaps small doses of the extr. cathart. for three or four days, or until bile appeared. He varied his saline medicines to Seidlitz powders, Cheltenham salts, soda tartar., or potass. tartar.; or he gave the cassia fistula; and this, with the occasional use of the warm bath, seems to have been his widest range of practice. That on the occasion in question Dr. Bone should have displayed sound judgment cannot be doubted, from his extensive experience for many years in the West Indies, and from the remarkable degree of tact which he has displayed on many practical points connected with yellow fever. How far any of the alleged advantages derived from this practice may be attributable to the views lately promulgated by Dr. Stevens, it is impossible to say, as the question of the advantages of the exhibition of neutral salts in yellow fever, on the principle of their immediate action on the blood, is involved in controversy. But whether in re-

ference to the exhibition of small doses of neutral salts as here spoken of, or to the popular remedies long in use in Spain, of large doses of the supertart. potassæ, or of olive oil or of castor oil, the difficulty always presents itself as to those means being generally applicable in a disease where the excessive irritability of the stomach forms so prominent a character. *Enemata* are very generally had recourse to as useful auxiliaries: one consisting of sea-water only was preferred by the late Arejula of Spain. In the West Indies and other places a proportion of the ol. terebinth. has been sometimes used with the other materials. At Gibraltar, in 1828, the employment of enemata of every kind was not unfrequently found impracticable from distressing excoriations which took place about the anus.

Mercury.—On a review of the different modes of practice adopted in this proteiform disease, within the last forty-two years, by practitioners in the British West India islands, the United States, and Gibraltar, this remedy seems to have best maintained its ground; for though it be quite true that it has from time to time fallen into discredit from persons having, in the course of an epidemic, frequently found that, like all other human means, it made no impression on the most aggravated forms of the disease, it nevertheless has stronger testimony in its favour than any other practice which can be named. The late venerable Chisholm said, after a consideration of the subject during thirty years, "Are we then, from any vain or unfounded apprehension, from reasoning drawn from false premises, or from uninformed or prejudiced minds, to yield up the result of our own frequently reiterated experience?—to relinquish the best aid [*i. e.* mercury] which we can bring to the support and relief of our fellow creatures suffering under so direful a malady?—Forbid it humanity!—forbid it heaven!"

Since the history of the American epidemics of 1793 and 1794, by Rush, numberless have been the publications in which the practice, either by inunction or otherwise, has been recommended, and the medical archives of our army and navy contain very strong evidence of the great advantage to be expected from the remedy in one shape or other (though not to the exclusion of other means) in those cases where a hope from the employment of any remedies can be entertained. Among the latest authorities in its favour is Mr. Linton, of the Naval Hospital, Jamaica, the gentleman before quoted as having had long experience in the West Indies. He states in his official report of December, 1829, that in his practice, after purging, the bath, and blisters, he gave calomel every two hours, in doses of from five to ten grains, and that, where the symptoms made rapid strides, he commenced mercurial frictions at an early period. He states in a previous report that, where he had been tempted, after the first calm from various remedies, not to push the mercury, he "had frequent reason to regret this *misplaced confidence*." He says, "In every instance, as soon as the mouth became affected by the mercury,

so that pytalism was unequivocally established, the patient might confidently be pronounced convalescent." He remarks, with great judgment, and in doing so he is perfectly borne out by the experience of others, that "there is, however, a condition of the gums, which are only to a certain degree affected by mercury, which is often confounded with pytalism, and which has frequently induced some medical writers, unacquainted with or prejudiced against the use of mercury, to affirm that several patients die in a state of pytalism. A strong mercurial halitus may be perceived; the gums are swelled, spongy, and livid, and a clammy, thick secretion of mucus, *not saliva*, takes place; but under these critical circumstances farther progress of pytalism is arrested." Under these circumstances, and the symptoms not yielding, Mr. Linton recommends that the internal use of the remedy should be suspended; that generous nourishment, warm baths, and stimulants should be had recourse to, and frictions then continued in the hope of obtaining the desired end. In one of his reports he alludes to trials of the medicine in a particular form: "in three cases which recovered under similar circumstances, I have latterly employed a solution of oxy-muriate of mercury with decided good effect; but when the stomach is very irritable, this form of medicine is inadmissible." Another gentleman of long experience in the West Indies, (Dr. John Arthur,) states in an official report from Barbadoes, of the 17th of March, 1821, "I believe far the most recoveries have been after the use of this medicine in one shape or other." It is stated in a report of the same year by staff-surgeon Hughes of Berbice, that calomel was given with "*great advantage*, and one satisfactory conclusion to be deduced from its operation, when it affects the mouth, was that of the patients being on the side of safety." In a report from surgeon Callow of the 84th regiment, relative to the Jamaica epidemic of 1827, he states that he "relied considerably upon the specific action of mercury for ultimate cure;" that he employed the blue-pill "certainly with advantage," and inunction as an invariable adjuvant. It has been stated by Dr. Francis, when referring to the treatment adopted in the epidemic of 1822 at New York, that "mercury was considered by some physicians as conspicuous among the curative means." The history of the Gibraltar epidemics furnishes the names of many experienced men who have seen good reasons for relying much on the use of mercury in this disease; among these, Mr. Amiel, now surgeon to the 12th regiment, should, perhaps, stand first. This gentleman having witnessed epidemics in that garrison at three different periods, and closely observed the effects of treatment the most varied, considered mercury, up to the last case in 1828, as his "*sheet-anchor*."

It is scarcely possible to name a British author on yellow fever whose views do not accord more or less with those expressed in the extracts here given. Mr. Wilson, of the Royal

Navy, the author of a work of great merit in many respects, published in 1827, when referring to the treatment even of those aggravated forms "where the nervous torpor and vascular atony are great, and where re-action is tardy, irregular, and imperfect; where the patient, without complaint of pain, lies prostrate, letting the head fall from the pillow, or pushing the pillow away, the countenance being ghastly, pale, or livid in colour, and fatuous in expression, the iris scarcely influenced by light,"—informs us that "calomel ought to be administered in most cases from the beginning; it should not be delayed beyond the operation of the purgative medicine. The quantity of this most valuable remedy and its manner of combination with others, must of course be varied according to circumstances; but the dose must on the whole be large and often repeated. If the character of the disease be not changed at an early period, its end will generally be in death." He adds, "with the other remedies recommended, I have given, and would give, ten, fifteen, or twenty grains of calomel twice or thrice daily, with a grain or a grain and a half of opium to each dose, according to the state of the digestive organs." The other means to which he here alludes are warm-baths of high temperature, ("above that which a person in health could bear,") and continued for some time, and assiduous friction after their employment; warm purgatives, combined with aromatics; warm drinks; warm stimulating injections; occasionally a little brandy, oil of terebinth in small doses; blisters over the epigastrium, between the shoulders, and to the head. He says that he was not deterred from this practice, in the forms alluded to, by the nausea and vomiting so characteristic of this fever. Like what occurs sometimes in the stage of re-action in cholera, he found it useful to abstract blood cautiously in the period of re-action following the low state of the animal energies here referred to. The *rationale* of Mr. Wilson's practice is extremely ingenious and well worthy of attention. He admits, as all must, "that in many cases the resources of our art have little influence on the disease, and that in its worst forms it is utterly beyond control." Indeed, it is not permitted us to be too sanguine as to the efficacy of any remedy in even a seemingly mild case of this "*perfidious*" disease; and the specific action of mercury, even after baths and aperients, will often fail to take place, the torpor of the absorbents being quite insurmountable; but as in an infinity of cases we can have no right to *assume* that this is the case, it must rest with the judgment of practitioners to decide how far they may be warranted in withholding a remedy standing so recommended as this does from various quarters.*

* The remedy was adopted by Palloni, in the yellow-fever epidemic of 1804, at Leghorn. Among the Spanish practitioners who have adopted it are Dr. Flores Moreno, of Cadiz, Dr. Ardevol, of Gibraltar, and Dr. Bobadilla, also of the latter place, who had experience in epidemics of Andalusia during thirty years, and who was so confident

Of one thing we have ourselves been convinced by ample experience, that though patients may often do well under other treatment, the medical attendant will be *infinitely less likely* to be taken by surprise, when pyæmia once sets in, by the sudden invasion of those symptoms which, within a couple of hours perhaps, are known to cut off a patient who seems to be in a state of convalescence, or nearly so. An objection is often made that, in the employment of these means, "*we lose time*;" and a very excellent objection it must be considered to be when it can be shewn that in the average of epidemics (for it is quite a delusion to speak of what takes place on particular occasions) other plans are found more useful.

Previous to dismissing the subject of the exhibition of mercury in yellow fever, it may be well to quote an observation from a gentleman in the West Indies, which goes to meet another objection sometimes made: "calomel does not, that I can perceive, produce any better effect in doses of twenty grains than in those of five; but even in very large doses I have *never* known it to cause hypercatharsis or any other bad symptom."*

The foregoing extracts are selected from a great mass to the same effect, as they complete the evidence that, up to the latest epidemics, mercury has been considered as holding a prominent place among the remedial means from which most hopes are entertained in yellow fever.

In the cases of profuse hemorrhage which frequently occur, the stomach is usually more retentive, and a bitter infusion, with a proportion of sulphuric acid, is found beneficial. The bleeding from the mouth is so excessive sometimes as to excite great apprehensions, but a strong solution of arg. nitr., applied very freely over the gums or other parts from whence blood is chiefly observed to flow, will often check it. In this stage of the disease every thing may be expected if circumstances admit of incessant good nursing, with the frequent supply, in small quantities, of nourishing articles of diet, as sago, arrow-root, broths,

of the remedy (chiefly in the form of inunction) that, on the invasion of the epidemic of 1828, he memorialized the governor of Gibraltar to be suffered to treat some of the military exclusively on his plan. The exhibition of mercury of late years by some of the best practical men in Great Britain and Ireland, not only in fevers *mali moris*, but in diseases purely inflammatory, including arachnitis, will probably tend to dissipate the prejudices of the French against the remedy. They have, indeed, already, by the admission of Messrs. Louis and Trousseau at Gibraltar, gained advantages from the adoption of mercurial frictions at Paris in puerperal peritonitis, a case of which seldom recovered under former practice there. Perhaps, too, as, according to the same gentlemen, two of every three cases of typhus die at the Paris hospitals, advantages might be looked forward to there by the adoption of the more energetic system of those British practitioners who find the exhibition of mercury diminish the mortality in this last disease.

* Surgeon Macdermot, 4th regiment. Official report to the Army Medical Board, December 20, 1821.

panado, &c., and wine or porter. This may be the place to refer to the hemorrhage from leech-wounds, formerly stated as likely to occur, and which it is extremely difficult to suppress when in soft parts, as the epigastrium; here minute bits of lint, dipped in the tinct. ferri mur., and pressed on each bleeding point by means of a probe, will be found more effectual than even the application of caustic in substance.

The occasional employment of other remedies, as saline draughts, sudorifics, opiates, ether, various cordials and aromatics, call for no particular remark. Where the remarkable "burning sensation" takes place, extending sometimes as high as the pharynx, from about the cardiac orifice of the stomach, calcined magnesia and prepared chalk have each afforded occasional relief; but these cases must be considered as utterly hopeless. When in the advanced stages great exhaustion has been produced by the incessant vomiting and want of sleep, a moderate dose of opium and capsicum, in minutely-divided pills, has sometimes produced a better effect than other medicines.

The most grateful *drinks* are spruce or ginger-beer, or a mixture of the white of egg, sugar, water, and some aromatic. As no small consideration in the management of patients, the *temperature of the hospitals or apartments* demands great attention. From what they have seen useful in other fevers, those unacquainted with the peculiarities of this disease are very apt to err on the side of over-ventilation, whereby, in some of its forms and stages, the vital energies are liable to be lowered perhaps to an irretrievable degree in an inconceivably short space of time; hence *tents*, or slightly-constructed huts, or temporary buildings are always objectionable. During the epidemic of 1828 at Gibraltar, a visit was made to one of the hospitals by Dr. Broadfoot, Mr. Amiel, and the writer of this article, when it was observed that in two of the wards an extraordinary proportion of the patients were doing well, and that in almost all these the specific action of mercury on the salivary glands had taken place. On inquiry it was established that, from an accidental circumstance, these wards were what might be called, *very badly ventilated*; and the circumstances altogether struck Mr. Amiel so forcibly that he instantly returned to his own hospital (12th regiment) and altered the plan of ventilation which had been previously adopted. This may at least be sufficient to draw attention to the point.

Contagion.—Those who have in the least entered into the subject of yellow fever must be aware of the total impossibility of giving, here, even a slight sketch of all that has been brought forward from time to time on this part of our subject. The discussions regarding a great mass of details, up to a certain period, may be said to be condensed in the works of Blane, Fellowes, and Pym, on the side of contagion; and of Bancroft, Jackson, Maclean, and Burnett on the opposite side. The elaborate works of

Dr. Bancroft especially (" *Essay on Yellow Fever*," " *Sequel to an Essay on Yellow Fever*,") embraced whatever could at the time be deemed the most essential points for consideration. From his analysis of the events of 1793 in the West Indies, as well as from statements furnished by other writers and the details given in the first part of this essay, it must be evident that Dr. Chisholm could not have been acquainted with the history of the disease when he stated that it made its first appearance in those islands in the year just mentioned. Dr. Bancroft's arguments against the importation of the disease in that year by the ship *Hankey* are greatly strengthened by the facts brought forward in a pamphlet on yellow fever by Dr. Veitch, of the Royal Navy.

It is usual to refer to Père Labat's statement of the alleged importation of the disease into Martinique, in 1682, by the ship *Oriflamme*, from Siam; to which it is objected that he has merely given vague reports of circumstances which occurred several years before his arrival in that island; and that if, as he states, the disease had been contracted at Brazil, where the ship touched, it was palpably erroneous to say that it had been imported from Siam. In the second volume, page 119, of Dr. Chisholm's work on the fevers of the West Indies, he gives an account, also, of an importation of the yellow fever into the island of Martinique while in our possession in 1796, which is very circumstantially proved to be erroneous in a paper to be found in the eighth volume of the *Medico-Chirurgical Transactions*, by Dr. Fergusson, inspector-general of hospitals, who happened to have served at the time with the troops on board the ship alleged to have imported the disease. There can be no doubt that among those who supported the views of Dr. Chisholm on contagion, respectable names are to be found; but even so soon after the periods to which he refers as 1801, when it fell to our lot to witness devastating epidemics in Martinique and Dominick, our experienced medical chief, Dr. Theodore Gordon, did not think it expedient to suggest any measures applicable to contagious diseases, nor did an apprehension upon the subject of contagion ever escape the lips of any of our seniors with whom we served. As regarded the men and officers on this occasion, an individual coming in contact with the disease for the first time could hardly, perhaps, form an opinion worthy of much attention; but a most remarkable circumstance was the *total* exemption of women and children under a certain age, as already noticed in the historical part of this essay, although no steps were taken in the way of precautionary measures.

In examining the official documents to be found in the office of the Army Medical Board in London, the following passage, contained in the report of inspector-general Tegart, dated 10th of March, 1823, is particularly striking: "In the various annual reports of the medical officers in this command, I have not seen one favouring or supporting the theory

of contagion: they are all on the other side." This seems the more remarkable, as isolation of yellow fever cases, to a greater or less extent, was a measure approved of a short time before by Mr. Inspector Green, one of those gentlemen who had previously served in the West Indies about the time of Dr. Chisholm.

Mr. Tegart, referring in his report to certain cases which occurred at Antigua in 1801, says, "The result is that this was decidedly yellow fever, and that the disease ceased on removal from the place, and was confined solely to those persons who occupied the room. Here is cause and effect." It must be admitted that, among the advocates of the contagion of yellow fever, very few are to be found in the West Indies in the present day.

Dr. John Arthur, however, in an official report from Barbadoes, of the 17th of March, 1821, furnishes a mass of details, the result of his own observation, favouring that side of the question; and although most of his details on this point may be considered by some as only *simulative* of contagion (the great error of former observers) as they relate to individuals exposed equally or nearly so to other general causes prevalent at the period, the document is one which deserves on every account to be referred to, and especially should a parliamentary investigation on the subject of the contagion of yellow fever be again instituted in this country. Among the few who have of late years advocated the doctrine of contagion in the disease as it prevails in the West Indies, surgeon Callow of the 84th regiment is to be mentioned. In an official report, detailing the events connected with the epidemic of 1827, in his corps, at Fort Augusta, Jamaica, he states that, after a certain time, "strong evidence of the disease propagating itself began to appear." His chief reasons for coming to this conclusion seem to be that the attendants about the sick of every denomination suffered remarkably, and that the surgical patients were also attacked. In the report itself, however, unbiassed persons will discover the following reasons for hesitating before they draw similar conclusions:—1st, he states, that previous to the breaking out of the epidemic, he made an official report on the defects of the building occupied as an hospital, and situated close to the *lagune*, whence disagreeable odours arose: 2dly, that, during the epidemic, the winds in the night "had generally blown from N.W. very strong for some hours, a very unusual circumstance," the more prevalent winds from E., S., or S.W., preserving, as he states, the low sandy point on which Fort Augusta is built, from more frequent sources of sickness. 3dly. He describes the barracks as being in three ranges or divisions, and that, up to a certain day, every case which occurred had been at the *extremity of each range of barrack*, "and in no other;" a very remarkable fact certainly. 4thly. It appears that, after his regiment removed from Fort Augusta to a camp-ground near Stony-Hill, it became healthy, any fresh cases being,

as he admits, traced to their origin in the Fort : some of the men confessed, indeed, that they had been ill previous to the move. Dr. Weir, physician to the forces, in commenting on these events, in an official report dated Kingston, February 13, 1823, remarks that "there are some circumstances connected with the history of the lately prevailing epidemic, which, viewed in the abstract, might seem to favour the theory that this disease is endowed with a self-disseminating property; but, on the other hand, such would appear to be far out-balanced by many powerful facts: of these no little weight is due to the simple and well-authenticated truth, that a change of *locule* invariably and almost instantaneously arrests the destroyer in its progress, and that too without any bad consequences, as is well instanced in the above, and in the removal of the 33d and 22d detachments to Port Royal, where the royal artillery occupied the very same barrack, without suffering in the slightest degree." We have, in the circumstances just referred to respecting the 84th regiment, several points within a small compass, which should never be lost sight of in the consideration of such questions. The exemption of hospital attendants, in the following instance, will by many be probably ascribed to the circumstance of the building occupied as an hospital having been in a more healthy situation than that of the 84th regiment at Fort Augusta:—"I have now, however, the heart-felt satisfaction of stating that, from the 20th of June 1821, to the 20th of February, 1822, which includes the whole period of the sickly season, not one medical officer, white servant, or person employed in any capacity in the Naval Hospital* establishment, who had been attacked with yellow fever, or any species of fever."†

Dr. Bone has resided in the West Indies for many years, and has from time to time drawn up elaborate reports upon yellow fever, frequently referred to by the members of the department to which he belongs; it may, therefore, be stated, for the benefit of those in search of information on this subject, that he says, in the same report, "the first important result which I have proved in the Naval Hospital is that the *yellow fever*, as it is called, cannot by any possibility be communicated from one person to another." He states that thirty-five white servants had been employed, and concludes by observing, "So few in the West Indies believe the doctrine [contagion] that they may very safely be permitted to enjoy their own opinions: they cannot do much harm."

We cannot pass over the official statements of Mr. Hartle, deputy inspector-general of hospitals, who has served in

the West Indies through the various grades of the medical department of our army, during a period of more than thirty consecutive years. His report for 1822 contains particulars of a most interesting kind relative to the introduction (without subsequent diffusion of the disease) of many cases of the yellow fever into the island of Antigua: in one place he remarks, "It is a pleasing reflexion, and a source of great gratification to me, that, notwithstanding one hundred and seven cases of yellow fever, as distressing and malignant as any I have before witnessed, have been by three vessels imported into this island since September 1821, we have not a single instance of any individual but those directly exposed to the local causes [ships] having been attacked." He states that the sick received on shore from one of those ships (Dasher transport) were attended by Europeans. Mr. Hartle's account of the yellow fever on board the Pyramus frigate, which arrived in Kingston Harbour from Barbadoes, with many of her crew affected with the disease, on the 3d of January 1822, is highly important. The following are the principal facts recorded by this gentleman. Neither the officers nor men had been exposed to solar influence or other exciting causes. One of the principal reasons assigned for the breaking out of the disease was that this ship had been "injected with coal-tar, which, with bilgewater, caused remarkable effluvia." The only ships on the station injected with coal-tar were the above, the Esk sloop of war, and Dasher transport, "all of which suffered, the former and latter especially, with a similar type of disease, yellow fever, in its most malignant form." He states that the crew of the Pyramus were landed and the ship dismantled. When the limber-boards were removed, the effluvia from the hold surpassed every thing which he had "ever before experienced." A boatswain looking into the hold from the lower deck, while an inspection by proper officers was going on, fainted, and passed afterwards through a formidable attack of the disease. Mr. Hartle himself, who was one of the officers appointed to examine into the state of the ship, escaped with slight indisposition. This gentleman states, respecting the others, that "every individual present at the opening of the holds and limber-boards was attacked by the prevailing disease." Although the frigate had been only six months from England, and was believed to have been a short time out of dock, four large mud-boats of filth were removed from her at Antigua, which was nine inches in depth in the hold. The negroes employed in removing this mass were obliged to go on deck occasionally, so insufferable was the stench, and three of them had the characteristic disease. The after-magazine, immediately under the gun-room, was found in the worst state, and this accounted, in the opinion of Mr. Hartle, for every officer's servant and servant of the gun-room mess having suffered. Objections hav-

* A splendid establishment, appropriated for some years past to the accommodation of the sick of the army.

† Official report from Dr. Bone, deputy-inspector-general of hospitals, Barbadoes.

ing been made to the removal of the crew beyond the dock-yard, after their landing on the 15th, several cases occurred up to the 30th, in consequence, as was discovered, of the men having gone on board clandestinely; the crew were therefore encamped at some distance from the dock-yard, while a cleansing and thorough purification took place; and, on returning on board, their general state of health continued good.

Within the last few years much valuable information upon yellow fever has been from time to time furnished by Dr. W. Fergusson, inspector-general of hospitals; and it is to be regretted that want of space precludes the possibility of extracting, as freely as would be desirable, from documents furnished by a gentleman of such great experience, tact, and candour. His paper in the eighth volume of the *Medical Chirurgical Transactions* is particularly interesting, and refers chiefly to transactions which occurred while he was principal medical officer in the West Indies, in 1816, &c. Dr. Fergusson is quite adverse to the doctrine of contagion in yellow fever; and it will be admitted, as we conceive, that the facts which he has adduced in the paper just mentioned, are calculated of themselves to make a powerful impression. He shews that, without restraint as to intercourse, situation alone has given great comparative exemption from yellow fever to raw soldiers from England over civilians; that the disease "is confined, in all the islands, to the sea-coast;" and that, "at Barbadoes, our hospitals, of late years, have been in a regular course of importation of the yellow fever from the navy; but not even inoculation has been able to produce the disease upon any member of the hospital corps, by whom I may truly say that the sick have been received with open arms; for the anti-social doctrines of ideal contagions are not preached among us here, to the prejudice of duty and humanity." Speaking of the general impression at St. Domingo, on the subject of contagion, during our occupation of that island, he says, "I never even heard the idea started, nor do I recollect a single precaution, advice, or observation, that acknowledged the existence of contagion, ever being directed to the medical staff from any quarter. I appeal to the writings of Dr. McLean, the living evidence of Mr. Weir, Dr. Jackson, Drs. Theodore Gordon, Borland, Inspector Warren, and all the medical officers who served there to bear me out in this assertion. I appeal to the evidence of every medical officer now serving in the West Indies, that has ever had experience of the disease (for there may very probably be found contagionists among those who never saw it) to say whether in their lives they ever met with a case of yellow fever that could with greater feasibility be traced to personal communication with a subject labouring under the disease, than to the ordinary natural causes from which it has been proved to originate." Dr. Fergusson's remarks go to corroborate the curious fact occasionally to be found in authors

as to "different parts of the same town being differently affected; and so limited often is their influence, that one story of a house,* or one section of a ship, will be strongly affected by it, while other parts of the same tenements remain healthy." In the paper from which these extracts are taken, will be found details of the highest value relative to the disease in question, as it prevailed among the crew of the *Regalia* transport, employed in carrying black recruits from the coast of Guinea to the West Indies in 1816; and from which it appears that the crew were in good health previous to taking in many tons of green wood at Sierra Leone; that great sickness (chiefly dysentery) prevailed among the blacks during the voyage; and that several deaths took place; but the yellow fever was altogether confined to the crew; and, in the words of Dr. Fergusson, "the ship, on her arrival at Barbadoes, was not put under restraint or quarantine, but communicated freely with the sea-ports of Barbadoes, the Saints, Antigua, and Guadeloupe; landing the severally ill or dying subjects of that disease amongst the inhabitants, and at the hospitals at Barbadoes and Antigua, without communicating infection at any of these places; and finally, after having undergone a thorough purification, sailing from Guadeloupe for Europe, crowded to a very great degree with rebel French prisoners and their families from the jails, under the most dangerous circumstances of health, with a case of yellow fever actually dying on board the day before she left Basseterre roads, but without communicating any such fevers to the unfortunate passengers, leaving any behind her at Guadeloupe, or importing any at the ports she ultimately reached." Dr. Fergusson, when speaking of an epidemic which took place in the following year, says, "what a different interpretation the facts I have collected would have borne, had the present epidemic that afflicts the islands broke out in the ordinary course of the seasons, a year earlier, at the time the *Regalia* was here." We shall only offer one more extract: "At Martinique they established a strict quarantine, particularly directed against Guadeloupe, and they have been consumed with yellow fevers; but at Dominique, Tobago, St. Vincents, &c. where they established none at all, they have not had, in as far as I have learnt, a single case, although at the last-mentioned islands both the *Tigris* and *Childers* ships of war imported distinct well-marked instances of the

* At Gibraltar, during the epidemic of 1828, we observed this to have been the case in a very remarkable manner in some instances; and Dr. Ramsay, surgeon to the forces, states, in an official report dated Barbadoes, 20th December, 1825, that, "in certain barracks and hospitals the very diagonal of particular apartments will afford a tolerably accurate demarcation of safe and unsafe position of beds." See on this point also Dr. Wilson's work on yellow fever (1827), in which the disease is shewn to have been confined to men whose berths were on a particular side, or in a particular part of a ship.

disease from *Point au Pitre*, on the evacuation of Guadeloupe."

Previous to closing this sketch of the question of contagion as connected with the importation of yellow fever into our West India colonies, it may be worth while drawing attention to an extract of a letter from Mr. Showers, ten years colonial surgeon of Sierra Leone, the first being the very year (1816) in which the *Regalia* sailed from that place:—"During my ten years' stay at Sierra Leone I never saw any other fever, [the ordinary fever of the country;] but when a fever broke out there similar to the yellow fever of the West Indies,* attended with black vomit, which was supposed to have been brought there from the Mediterranean by a ship called the *Caroline*, this I recognised as a different fever from the one I have just described, from the common fever of the country; and to my knowledge none of the medical men then at Sierra Leone had any difficulty in distinguishing it as a new and different disease."† Mr. Showers adds, at the close of his letter, that respecting the fever of 1823, he had "his doubts whether it was imported or contagious; I am much of opinion that it proceeded from the atmosphere;" which doubts he was the more justified in entertaining from the known fact that for two years previous no yellow fever epidemic existed at any port in the Mediterranean. To those who had been led to believe that the true black-vomit fever had been not unfrequently exported from the coast of West Africa, its reputed birth-place, this visitation as a perfect stranger, and its alleged importation from Europe, must appear somewhat strange. The healthy state of the *Regalia* transport previous to her sailing from Sierra Leone, together with what appears by Mr. Showers' letter as to the non-existence of the yellow fever there in 1816, would seem to favour Dr. Fergusson's idea of its having been produced by the great quantity of green wood‡ just laid in previous to her sailing, and to "foul ballasting that had not been changed for years." However it may affect the question of contagion, it would, considering the mass of evidence now before the public from various sources, be quite idle to deny the spontaneous breaking out of yellow fever on board of ships in the West Indies, and, more rarely, in other places: one of the best authenticated instances is that of the *Bedford*, seventy-four, in Gibraltar-Bay, so far back as 1794, of which there are official records at Somerset House. In that year yellow fever was not prevalent in the garrison, and the crew arrived in perfect health from the Mediterranean on the 24th of August. On Sunday the 6th of September, the crew having been mustered,

* The year 1823 is here referred to.

† See Mr. Showers' Letter, dated Malta, 27th July, 1830, in Dr. Aiton's *Dissertations on Malaria*, &c. 1832.

‡ In the official report of Mr. Hartle, lately referred to, it is stated, on the authority of Mr. Mortimer of the Royal Navy, that the *Nayden* frigate having taken in green wood at Dominica, lost one-third of her crew by fever.

every man answered to his name; but in the course of the week one hundred and thirty were sent to the hospital, with fever possessing the characteristic symptoms: eleven died before the 24th of September, and others were left dangerously ill on the departure of the ship that day. In this case the only feasible cause assigned was the shifting of the shingle ballast, after the ship arrived, with the object of *trimming* her. The disease did not extend beyond the sailors of this ship. The fact, (considered at one time as an indubitable proof of the propagation by contagion,) of the sailors of the British brig of war *Carnation* having been attacked with the disease when put on board the French brig *Palinure*, by which she was captured, near Martinique, in 1808, as stated in the *Dictionnaire des Sciences Médicales*, would admit of the explanation of their having, in common with the previous cases existing in the *Palinure*, originated from sources within this ship, and independently of persons. The following is among the most recent instances of the spontaneous irruption of black-vomit fever on board ship. His Majesty's ship *Blossom* had been for some time employed in the summer of 1830 in surveying the Honduras coast; and in the month of August the disease commenced, which obliged the captain to go into Belise harbour, to obtain medical assistance from the garrison, into the military hospital of which forty-eight cases were received between the 11th and 30th of August: two officers and eight men died, and "these cases were attended with black vomit," according to the gentleman who had charge of them, assistant-surgeon Watts, of the second West India regiment, who had previously served in Jamaica, and who forwarded notes of the circumstances in his official return to the Army Medical Board for the quarter ending the 24th of September, 1830. Mr. Watts adds that the disease did not extend to the other ships, or to persons on shore. In a report from Dr. Lindsay, surgeon of the *Blossom*, to the heads of his department, relative to the event in question, he says, "I am of opinion that the cause of the present illness arose in the ship herself." Among the naval surgeons of the present day, of practical knowledge in this disease, we do not find many supporters of the doctrine of contagion; and among the observations on this point published of late years, Dr. Wilson's stand pre-eminent. The following from Mr. Mortimer, while serving as principal naval medical officer at Barbadoes, are forcible: "We do not allow the fever of the West Indies, commonly called 'yellow fever,' to be at all infectious in any of its forms or stages. We have never known of an instance of its communication to patients at the several naval hospitals, whilst under cure for other complaints, though such patients have never been interdicted, on the contrary encouraged to offer every additional aid for the greater comfort of their suffering brethren."*

* See Communication to Commissioners of Transports,—*Med. Chir. Rev.* vol. viii.

Passing now to the American continent, our limits admit but of a few brief remarks. Up to the year 1793, almost all the medical men in the United States were believers in the communicable nature of yellow fever; but each successive epidemic diminished the numbers, so that in 1825, according to an American commercial almanack, while five hundred and sixty-seven were against the doctrine of contagion, twenty-eight only remained in favour of it, throughout the whole country; the latter number being in all probability now reduced, as some of those mentioned were very aged. The public manner in which the celebrated Dr. Rush, once a believer in contagion, retracted his opinion, after farther observation, is matter of historical notoriety. At New York the doctrine of contagion is still ardently supported by two physicians in particular,—Professor Hossack and Dr. Townsend, who have both written much upon the disease. The facts which presented themselves to Dr. Beck in the course of the last epidemic at New York (1822), caused his public retraction of faith as to contagion in the following year;* and Dr. Townsend appears to have admitted† that, of about two hundred persons of all grades of the profession in that city, three or four only believed lately in the transmissible nature of yellow fever. “In 1793 the profession were almost unanimous in the belief of its contagious character, and no little courage was required to brave the storm an opposite opinion would have awakened. In this generation an equal unanimity prevails in the profession as to the non-contagious nature of the disease; and he who advances the opposite doctrine seriously, is deemed no more worthy of notice, much less a refutation, than would be an advocate at this time of the Ptolemaic system.”‡ Upon this highly important question, the following unpublished statement from the pen of M. La Roche, French consul at Philadelphia, cannot but be important: it is extracted from a letter, which we have had in our possession, to a friend of his in Paris, dated the 20th of July, 1830. “A friend of mine, Dr. Morrel, has lately arrived from the Havannah. During a few days’ passage three persons died of yellow fever on board, and a fourth, taken ill on board, died in the New York quarantine establishment. The sick were all *cabin passengers*, and received the germs of the fever in the port. The other passengers, who merely embarked at the moment of departure, without having waited in port, remained well, and that notwithstanding the inevitable contact arising from twelve or fifteen persons sleeping in a small cabin. Dr. Morrel and the other passengers were placed in quarantine, but during the time every body went to see them.”

Much interesting matter relative to the evi-

dence on the subject of contagion in the yellow-fever epidemics which have from time to time prevailed in America, may be obtained by consulting various pamphlets published by Dr. Chervin of Paris, who has made the subject of yellow fever his particular study for many years of his life. In those pamphlets will be found evidence of zeal in the cause of science quite unparalleled, as well as of impartiality in his proceedings in search of truth. It is quite impossible, in the present day, to meet the subject of contagion of yellow fever fully, without a knowledge of the nature and extent of his researches. Here, with a view of shewing their value, we may give a few extracts from the commission appointed by the Academy of Sciences in Paris, in 1827, to adjudge the prize designed for labours in medical science. The *commissaires* were MM. Portal, Boyer, Chaptal, Dumeril, Dulong, Gay-Lussac, de Blainville, Frederic Cuvier, and Majendie.

The report made by the above gentlemen, after stating some unusual steps taken by Dr. Chervin to ascertain the contagious or non-contagious nature of the yellow fever at Guadaloupe, to which place he had proceeded from Paris, for the sole purpose of making investigations, proceeds thus:—“This is nothing!—It was, on the contrary, then that Dr. Chervin conceived the wisest and vastest plan that ever a medical man formed for the interests of humanity.

“It was no longer sufficient for him that he had satisfied himself that the yellow fever was not contagious in Guadaloupe; it became necessary to ascertain whether it did not possess that character in other localities and in other latitudes and climates. It was above all things necessary to convince the governments of Europe, so that commerce might be freed from unnecessary precautions, felt to be burthensome, and that nations might be saved great expense in sanitary establishments. In attaining his object, Dr. Chervin was only impelled by his ardent philanthropy—no other means, but the sacrifice of his patrimony—no support but his own inclination and physical powers—let it be declared, to the honour of humanity, that by such means alone enterprises of this kind could be accomplished; and in fact, what a powerful government could scarcely hope to obtain at great expense, Dr. Chervin proposed to himself to obtain.

“Dr. Chervin performed this gigantic undertaking, to which the history of medicine furnishes no parallel, in a fortunate manner, but with unheard-of efforts, and perseverance above all praise.”

Speaking of his having collected the evidence of hundreds of medical men in all parts of the world where the yellow fever is known to prevail, the report continues—“He visited, in eight years, all the colonies belonging to France, England, Spain, Holland, Denmark, Sweden: he visited all parts of North America, where the yellow fever has shewn itself, from New Orleans to Portland, in the state of Maine; so that from Cayenne to this last place he tra-

† Chervin. De l’Opinion des Médecins Américains, p. 11.

‡ See Amer. Journ. of Medical Sciences, August, 1829, p. 523.

versed over and made investigations in 37 degrees of latitude."

"It [the commission] therefore proposes to adjudge him a prize of 10,000 francs: undoubtedly a poor reward for the many sacrifices which he must have made; but when a person has, like Dr. Chervin, merited so much from science and humanity, and shewn such disinterestedness, *on voit la couronne et non pas sa valeur.*"

In a work of high character* Dr. Chervin's labours in the cause of truth are thus alluded to: "Observe, in regard to this last subject, [viz. the error of attributing to contagion what should be referred to local causes,] what occurred respecting the yellow-fever epidemic of 1821, in the unfortunate city of Barcelona. Read the work of the French Medical Commission† appointed to examine into that epidemic, and it will be impossible for you (admitting as true the statements therein contained) not to admit the existence of contagion. But afterwards, when you have read the precious documents collected by Dr. Chervin with a degree of zeal and patience truly admirable, you will rest convinced that the circumstances which led you to be of the same opinion with the commissioners as to the reality of contagion, are any thing but conclusive; thenceforward the idea of contagion will be effaced from your mind, *comme un vain songe*; and, pressed on every side by the evidence of observations, you will be compelled to attribute to *local infection*‡ those circumstances which, misled by inaccurate statements, you had placed to the account of contagion."

That in North America the disease has not been propagated by the removal of persons labouring under it, even when carrying with them their bedding, &c. has been shewn by observations made there during many years by medical men (some even professed contagionists), in instances of upwards of thirty cities and towns, according to a report upon Dr. Chervin's documents, read at the Academy. By those documents it also appears that attendants of all classes on yellow-fever patients constantly remained exempt from the disease in that country, *where the hospitals were placed out of particular local influences*. This it appears was the case at the hospital at Bush-hill, near Philadelphia; in that of Belle-vue, near Fort Stephens; in that of the navy at New York; also in those of Norfolk, Baltimore, Providence, Newport, Boston, and New London. These most important facts are verified by Drs. Chapman, Redmond, Cox, Mease, Lehman, Mitchell, Parish, Jackson, Perkin, Miller, Tucker, Thomas, Backe, Harlon, Coates, &c. of Philadelphia; by Drs. Anderson, Brown, Walker,

Drake, and Osborne, of New York; by Dr. Archer, of Norfolk; by Dr. McCauley, of Baltimore; by Dr. Weaton, of Providence; by Drs. Turner and Waring, of Newport; by Dr. Townsend, of Boston, and Dr. Lee, of New London. Proofs to the same effect, collected in the West Indies, were laid before the Academy in 1827, by Dr. Chervin.

Dr. Pariset, medical chief of the quarantine department in France, has admitted that the yellow fever "is not contagious in America,—whether it had ever been so, or has ceased to possess that property."*

With respect to South America, the points bearing upon this part of our subject have perhaps been more fully entered upon by Humboldt than by any other person. In his Political Essay, (vol. iv.) he mentions that at Vera Cruz the idea of the importation of the disease from the Havannah and other places had been from time to time entertained; but by the facts which he furnishes, there seems to be no reasonable cause for doubt as to the disease being indigenous at the former place. The subject of contagion is investigated by this celebrated man in the spirit of philosophy for which he is so remarkable: we are shewn by him to what an extent one test of the communicable nature of a disease—that of taking people, actually ill of a disease, into healthy districts—has been applied, and the result proved to be entirely against the doctrine; that not only at Xalapa, and higher up in the interior, but at the farm of Eucero, a short distance from Vera Cruz, the disease is found to confine itself to the persons of those who may arrive with it in their systems from the latter place, notwithstanding the freest intercourse with others. Every observation made by Humboldt throughout his works, relative to yellow fever, is of high interest: one seems peculiarly deserving of attention; which is, that although the disease usually prevails among the newly arrived every year at Vera Cruz, it never prevailed epidemically there between 1776 and 1794, although the intercourse with the Havannah and other places where the disease continued to prevail, was quite free. He even says that during the eight years preceding 1794, "there was not a single example of the *vomito*, although the concourse of Europeans and Mexicans from the interior was extremely great, and the sailors gave themselves up to the same excesses which are now laid to their charge."† Such a fact is the more worthy of notice, as it does not appear to have depended on unusual atmospheric states during this period; and one can scarcely concede any very great degree of importance to the circumstance of the streets of that city having been for the first time paved in the year

* Dictionnaire de la Médecine et de Chirurgie, vol. v. article *Contagion*.

† At the head of which was, be it remembered, Mons. Pariset, Medical Chief of the Quarantine Department.

‡ We know that in France the word *infection* is exclusively applied to *places*, not to transmission of a disease, directly or indirectly, from person to person.

* "N'est point contagieuse en Amérique, soit qu'elle ne l'ait jamais été, soit qu'elle ait cessé de l'être." Bulletin des Sciences Méd., tom. xii. p. 126.

† Political Essay on the Kingdom of New Spain, vol. iv. p. 194. Dariste, who practised in Martinique for some years, informs us of a similar exemption at that island between the years 1807 and 1816; and that old inhabitants remarked intervals of even twenty-five years between epidemics.

1775, seeing that the disease has recurred so often since 1794, and has prevailed so frequently in the well-paved streets of St. Pierre Martinique, of Cadiz, Seville, Gibraltar, &c.

To turn now to a view of the question as to whether this disease has been proved in Spain to have possessed the property of propagating itself from person to person, immediately or mediately, it appears that so far back as 1761, (21st October,) a royal edict was issued at Madrid, which set forth that all experience of the intercourse between the Havannah and Cadiz had proved that the black-vomit fever was not contagious. It would appear from this that the opinion of the court physician Cervo, sent to inquire into the nature of the Cadiz epidemics of 1730 and 1731, had been more regarded than that of Navarette, who attributed their origin to importation from America. It seems very curious that the late Dr. Arejula of Cadiz should, when he wrote his work on yellow fever in 1806, and which is so valuable in many respects, have laboured under the great error of the black-vomit disease of the Havannah, Vera Cruz, &c. being a different disease from that now so generally known by the name of yellow fever, and admitted to be identical. He appears in the strange dilemma of contending for the contagion and importation of the disease under one denomination, (*yellow fever*,) while he admits freely that in America "a succession of ages proved to the medical men that the disease was not communicable:"—and speaking of Spain, that "our ships never brought the germs of the black-vomit, even though they had the disease on board when leaving our possessions." This physician, with Drs. Coll and Amellor, also of Cadiz, made a declaration that the medical men commissioned to inquire into the causes of the epidemics of 1732 and 1734, pronounced it not to have been propagated by contagion. In all subsequent epidemics, a great majority of the Spanish practitioners have favoured the doctrine of importation and contagion; but it would appear from the assertion of Professor Salva of Barcelona, in his *Trozos ineditos*, that the public opinions of some had been influenced by political or other causes, for he does not hesitate to state, that when with a view to illustrate the subject of the contagion of yellow fever, he applied for information, private opinions as to its not possessing that property were obtained from some of those who had publicly declared the contrary. A commission, instituted at Cadiz to inquire into the origin of the epidemic of 1810 in that city, declared that in none of the six epidemics which had appeared previous to 1805, could the origin of the disease be traced.* The importation of the disease allowed to by the commission as having taken place in

1805, had reference to the disembarkation of about two hundred cases from the fleet of Admiral Gravina on its arrival from the West Indies. The commission admit that though many of the cases had the most characteristic symptoms, and though the communication with the city was completely free, "the disease did not spread, nor was it in any way communicated." It is also stated that though many cases were sent to the Aguada Hospital at Cadiz from a French fleet in 1807, with which a free communication was permitted, the disease did not spread. In addition to the authorities cited at the commencement of the present subject, many details connected with the origin of yellow-fever epidemics in Spain up to the year 1820, and which cannot possibly be entered upon in detail here, are to be found in Hurtado's "*Nueva Monografia*;" in his "*Decadas*;" in Mr. Doughty's book; in the writings of Dr. Pariset; and in various pamphlets published in Paris since 1827 by Dr. Chervin.

Regarding Gibraltar in particular, we may be allowed to state that a residence there within the last few years brought us into frequent contact with a gentleman who had been present during the existence of the disease in the years 1810, 13, and 14,—Mr. Amiel, many years on the medical staff of Gibraltar, and now surgeon to the 12th regiment. The evidence of this gentleman, comprising the fullest details upon every point, goes to refute the statements made regarding the importation of the disease at any of the periods in question, and is fully corroborative of the evidence upon the subject placed before the public by Sir W. Burnett and Dr. Bancroft. The only forms in which Mr. Amiel's statements have come before the public are, a short memoir printed at Gibraltar, and a paper to be found in the Edinburgh Medical and Surgical Journal for April 1831. We have been assured by him that the impression given* by the present superintendent of quarantine in this country, as to the disease having been cut short in 1810 by his recommendation of segregating the cases, is utterly fallacious; for, as has also been specially certified to us by Dr. Bobabilla, another practitioner resident during many years in Gibraltar, the progress of the disease was stopped, *as it is always found to be*, by the setting in of a cold wind from the north. It must be obvious that placing a point like this on its true footing is of the highest importance to the public. Notwithstanding the body of evidence on record against contagion in all the Gibraltar yellow-fever epidemics up to the year 1814, and though from Bancroft's works it appears that among the medical men of that garrison the majority of opinions had been greatly against it, it was nevertheless impossible that unbiassed persons should be uninfluenced by the statements published by two officers of the quarantine department,† who, having been on the spot, had ample opportunities of arriving at the truth on

* "En ninguna de estas epocas, exceptuada la de 1805 en que vino de fuera, se ha podido averiguar con exactitud, el origen de esta calamidad publica." "At none of these periods, except 1805, (in which it was imported) could the origin of this public calamity be determined with exactness." *Extract from the Report of the Commission.*

* See Pym on the "Bulam" Fever.

† Ibid.—Fraser's (W. W.) Letter to Lord Chatham.

such points. The circumstance here alluded to is the assertion that, during the epidemic of 1813 at Gibraltar, the people employed in the dock-yard there, having been strictly separated from the rest of the garrison, remained free from the disease. Here, then, was evidence fully in support of the utility of quarantines, and of the propriety of separating, on future occasions, the healthy from the sick. But what was the astonishment of the profession on finding that mis-statements had here taken the place of facts, as shewn by Dr. O'Halloran,* who had served in a regiment at Gibraltar for some years subsequent to the period. During a residence at Gibraltar, we had ample means, by referring to the declarations of the official authorities at the dock-yard, of confirming the assertion of Dr. O'Halloran as to several cases of the fever prevalent in 1813 having occurred there, as well as some deaths; indeed the names of twenty-three (of which seven proved fatal) could be here given were it necessary: so that regarding the original statements, no impressions favourable to the accuracy or candour of the quarantine officers who made them can be entertained; and in the justly severe remarks of Dr. O'Halloran on the subject, to which no reply has been made, future observers of circumstances connected with the public interest have received a salutary warning.

The terrific epidemic of 1831 at Barcelona gave a new impulse to the question of the contagion of yellow fever. The statements furnished by the medical commission sent from France† to make researches into the nature and origin of that disease, left a strong impression on the minds of many in the profession favourable to its possessing a communicable property; and the "*Histoire Médicale*" displays literary powers of a high order on the part of Dr. Pariset, who was at the head of the commission. The same gentleman, however, (Dr. Chervin,) who had devoted so much time and labour, as already shewn, in procuring authentic information in the West Indies and America relative to the question of the transmissible nature of the yellow fever, followed Dr. Pariset step by step some time after, not only at Barcelona, but through all parts of Spain where circumstances had been detailed respecting the propagation of the disease. The result has been,—not a mere series of assertions against assertions,—but a collection of documents duly authenticated, such as had never before been laid before the public on any question of this kind. As elucidating a long-pending question of high importance to society, their value may be judged of from the opinion of the Academy of Medicine, which has been already referred to. We regret that space will not permit our furnishing many valuable extracts from the works of this gentleman, pub-

lished in 1827 and 1828.* We are furnished with the statements of Dr. Pariset and others regarding a multiplicity of events connected with the appearance and progress of the yellow-fever epidemics of Spain; and it cannot but be admitted, we think, that Dr. Chervin has shewn, in a manner the most conclusive, that many inaccuracies had crept into those statements, and that the events warranted conclusions quite opposite to those which had been come to. Dr. O'Halloran, who went to Barcelona to observe the epidemic of 1821, had, previously to Dr. Chervin's visit there, pointed out some of the most important errors of Dr. Pariset; and in his book, already referred to, some interesting statements are furnished relative to occurrences at other points.

An event very remarkable in the history of yellow fever, and but little spoken of in England, occurred in 1823 at the little port of Passages in the province of Guypuscoa, a place well known to many British naval and military officers, it having been the rendezvous for transports while the British troops occupied the Pyrennees in 1813-14. It is difficult to give an idea of this singular port, situated at the bottom of the Bay of Biscay, and forming a sort of appendage to St. Sebastian's, from which it is distant but a very short way. The entrance is between precipitous rocks, and is so narrow and oblique as to be with difficulty discoverable at a very short distance. This miniature town consists for the most part of one small street, placed as it were on a shelf of scarped rock, and so narrow that it does not admit of the passage of carts or horses, while the rock forming the base of the mountain of Olearso is in some places literally in contact with the houses, which are badly ventilated, filthy, dark, and crowded. Let us take the events in question from the account given of them by Dr. Arruti, a physician long resident in that part of the country, and who, while he would lead us to believe in some places that he considered the disease within certain points contagious, yet relates the facts which took place under his observation with such perspicuity and candour, that it is impossible to perceive the smallest intention on his part to mislead. We are informed that, in June 1823, a brig named Donostiarra sailed from the Havannah with a clean bill of health; and that, having lost one man on her voyage, (from ordinary disease as far as was known,) she obtained pratique in the usual way at Corunna, after ten days' quarantine. She subsequently put into St. Andero, and arrived at

* O'Halloran on the Yellow Fever of Spain, p. 168.

† Dr. Pariset, medical chief of the quarantine department, with Drs. François and Bally. This is not an occasion to enter on the alleged political motives by which this commission might have been influenced, with a view to favouring the adoption of the famous *cordon sanitaire*, previous to the invasion of Spain in 1822.

* In the "*Revue Critique*" by Dr. de Fermon of Paris, printed in 1829, a *resumé* of the occurrences here spoken of may be found.—Dr. Reider of Vienna, who has also made yellow fever the subject of particular investigation, and undertook, for the purpose, voyages at different times to the West India Islands and the American continent, states, in a memoir published at Vienna in 1828, that the disease "was never imported into Europe or anywhere else;" and that "it never originates in, or is propagated by contagion." He deploras the manner in which governments are misled, and the best interests of humanity sacrificed, by those who endeavour to maintain the present system of quarantine.

Passages on the 3d of August, with all on board in perfect health. This vessel had been latterly employed in the trade of these ports. As she had been at Corunna and St. Andero previous to her arrival at Passages at the date just mentioned, she was not put into quarantine at the latter place. The cargo, consisting chiefly of sugar and tobacco, was discharged soon after her arrival; and for several days a great many people of all classes went on board, but without any disease having broken out among those individuals, among the crew, or in the part of the town where the cargo had been deposited. On the 15th, a custom-house officer, who had been several days on board, was taken ill, and he died on the third day, black-vomit having appeared. This man was said to have been much engaged in the hold looking after contraband goods. On the 22nd, a man who had been down for some time in the hold surveying the ship's timbers, likewise died. Some of the planks of one of this vessel's sides having been found greatly decayed, twelve carpenters were employed in removing them, and six of the twelve were attacked in quick succession. The opening in the side of the ship commenced on the 19th, and on the 23d the disease began to appear in an unequivocal form in the houses close to which she was moored. Dr. Arrutti proceeds to shew in *detail*, and in the most satisfactory manner, that the disease did not extend beyond a certain number of houses at or near the *Plazuela de la piedad*, opposite the ship; that where others were attacked whose habitations were at a distance, it was occasioned by their having remained for some time within the space to which the malaria from the ship appears to have been limited, and the names and occupations of those persons are given. The heat was excessive in the middle of September, being, as he states, $28\frac{1}{2}^{\circ}$ Reaumur, (about 96° Fahr.,) and the course of the wind favoured the conveyance of the noxious emanations from the ship to the houses near it: he gives the number of each house in which persons were attacked, and names the points beyond them to which individuals labouring under the disease went, and where, notwithstanding the adjuncts of *crowded, filthy, and badly-ventilated habitations*, the disease did not spread beyond the individual: for, as he says, "whether they died or recovered, to none out of the focus was the disease communicated."* In the same page he says, "The inhabitants of Passages took the precaution of not making long delays in the focus of infection; they visited their relatives and friends, and performed towards them all the rights demanded by humanity and society, and the disease became extinct almost in its very origin." He observes, "It therefore results that this fever, examined according to the character it presents, does not offer a character of contagion from individuals."† And again, "It was afterwards discovered that many, evading the sanitary regulations, passed out without certificates of health, and took with them clothes, even from the houses where people had died; but notwithstanding this,

there was not the least spreading of the disease in the neighbouring country. If any deaths took place in Loyola, Renteria, or elsewhere, the disease in such cases had been contracted within the focus of infection." Finally, Dr. Arrutti observes, "If this disease had been transmissible by individual contact, what could have put a stop to its progress?—no human power: for the people who had been in the closest contact with sick, convalescents, and clothes belonging to the sick, distributed themselves, when the cordon was about to be placed, at St. Jean de Luz, St. Sebastian's, Bayonne, and other places." Here then, as we are necessarily obliged to conclude, is an instance—not of yellow fever imported,—nor, rigidly, of the cause of yellow fever imported, but a development of the disease by the concurrence of a certain number of agents. On other occasions yellow fever has been observed not to break out until vessels had been cleared of their cargoes; and in this instance the great heat which is stated to have occurred, reverberated as it must have been from the mass of rock close to which the lightened ship was moored, may be easily understood as having been highly favourable to the extrication of a noxious principle from her decayed planks.* In another account of this epidemic, given by Dr. Montes in the 14th vol. of *Hurtado's Decadas*, its origin is attributed to sources within the town itself, and totally independent of the ship, as publicly declared at the time by Dr. Zeubeldia; and that a similar epidemic prevailed there in 1780.† There is no discrepancy, however, in the statements as to the disease not having been propagated from person to person; though, as before intimated, Dr. Arrutti seems to apply the word contagion‡ to the extension of the disease within the limits of the noxious emanations from the ship. It appears that no inspection, such as took place in the case of the *Pyramus*, had been instituted here. From Dr. Arrutti's statements we can now comprehend the possibility of some fever cases having occurred among the men of this last ship, while they were living in the

* The origin of this disease at Passages, from sources on board unconnected with the death of the individual during the voyage, has been, on one occasion at least, admitted by Dr. Audouard of Paris, a professed contagionist.—See *Revue Médicale*, Sept. 1824, p. 38.

† We were not aware that yellow fever had appeared at any other point on this part of the Spanish coast, till looking over lately the official report from Dr. Bone already referred to. This gentleman says, "At St. Ander, in 1813, none of my assistants, orderlies, [army attendants on sick,] or nurses, employed with the cases of yellow fever treated in the *Casa blanca* in the quarantine hospital, were attacked with it."

‡ We had been long in communication at Gibraltar with a Spanish practitioner of great experience, (Dr. Bobadilla) and considered him for some time a believer in contagion, in the sense of direct or indirect transmission of a disease from one person to another; but to our surprise he assured us, that, at an hospital in Los Barrios near Gibraltar, some years ago, he explained to every body how the attendants of all classes on yellow-fever patients were not more liable than others to attacks.

dock-yard at Antigua, even without their having, as stated, gone on board secretly.

As, in the same year in which the above occurrences took place at Passages, another remarkable circumstance occurred, which has been frequently alluded to, it may be here mentioned, previously to referring to the events connected with the subject of contagion in the last epidemic to be noticed.

By an official report drawn up and published in 1824, by Dr. (now Sir William) Burnett, one of the commissioners of the Medical Department of His Majesty's Navy, it appears that in the early part of the preceding year a fever made its appearance at Sierra Leone in a form different from the usual remittents of the country, and stated to possess symptoms characteristic of yellow fever. The importation of this disease by the merchant-ship *Caroline*, as at one time alleged, is completely refuted in this report; and at page 24 an extract of an official document from the gentleman at the head of the medical department at Sierra Leone is given, in which it is stated, that from all the evidence which could be procured in the colony, there was reason to conclude that the disease was *non-contagious*. A curious circumstance, to which there is perhaps no parallel on record except that which, as formerly stated, occurred under our own observation in the West Indies in 1801, is related by this gentleman, viz. "that European females and children were perfectly exempt."

Under date of the 23d December 1823, a statement was circulated through the army by Sir Gilbert Blane, calculated certainly more than any thing which had previously appeared to prove the importation and subsequent diffusion of yellow fever by persons labouring under it. It appears that His Majesty's sloop-of-war the *Bann* left Sierra Leone for the Island of Ascension at the latter end of March, 1823; that a malignant fever, of which several died, prevailed among her crew, during and for some time after the voyage; and that, on the eighteenth day after her anchoring at Ascension, a disease alleged to have been similar, and in some instances accompanied with black vomit and yellow skin, broke out in the small force composing the garrison of that island, which consisted of thirty-five individuals, officers and men of the marines and artillery, besides women and children. It appears by the details given in Sir William Burnett's report, that an error (of little importance perhaps) had crept into Sir Gilbert's statement regarding the perfect health of the crew of the *Bann* when she left Sierra Leone; but what is of very great importance has been omitted by the latter gentleman in his letter, though supplied in the very candid statements of the former,—viz. "On reference to the journals of medical officers who at different times had charge of the garrison before the appearance of the late epidemic, an abstract of which is in the Appendix, not only has dysentery and hepatitis been very prevalent, as well as occasional attacks of fever, but likewise a fever called the bilious remittent, in the year 1818, attacked almost every man on the island,

which the assistant-surgeon attributes to an unusually wet turtle-season, when the men are much exposed by watching at night to turn these animals. Moreover there is, in the journal of Mr. Robert Malcolm for 1818, a case of this disease, which commenced on the 1st of June, and terminated by death on the next day, with all the symptoms of yellow suffusion and black vomit, &c., which are said to characterize the yellow fever; and having shown this case to the surgeon of the *Bann*, now in London, he declares it to be exactly similar to the cases of fever which lately proved so fatal in the *Bann*, and amongst the marines at Ascension."* Here then, whatever might have been the nature of the disease which prevailed in the *Bann* and at Ascension in 1823, we have evidence of the existence of the same disease in the island, and about the same time of year, in 1818, without the remotest suspicion of its having been then imported. This, on the obvious principle that what may in one year happen on a small scale, may, from an extension of the cause, happen on a larger scale in another year, greatly enhances the force of the concluding part of Sir William Burnett's sixth position, "that a disease similar to the fever in the *Bann* might have prevailed in that island though the *Bann* never had any communication with it."† He tells us that "the principal medical officer at Sierra Leone has come to the same conclusion in his official report;" and we suspect that, closely investigated as questions respecting the present subject have lately been, and greatly augmented as the facts bearing upon the question of contagion have been within the last few years, the majority of the profession who have paid attention to yellow fever will be likely to come to the same conclusion, rather than admit as a *propter hoc* that which, as far as any evidence goes which has yet appeared, was simply a *post hoc*. Sir William, though favouring, under all the circumstances, the belief of the importation of the disease on the above occasion, candidly leaves the question open, and furnishes all the details within his reach, to enable the profession to form an opinion. He points out erroneous statements as to the particularly healthy state of the island from the period of our occupying it (1815) to the epidemic year 1823. He says, "Out of one hundred and thirty cases of disease which are recorded in these journals, twelve died and nineteen were invalided; and though perhaps all the fatal cases are inserted in the journals, it is well known that those documents seldom contain more than a third of the cases which actually occur." He tells us that, although, at the time of the arrival of the *Bann*, the little garrison was in good health, and that, according to the medical gentlemen in charge, although at a period immediately preceding this event "they were on the whole very healthy, yet they were by no means exempt from disease."‡ He admits "that after a most careful inquiry it is impossible to trace the fever in question

* Page 10.

† Page 52.

‡ Page 11.

directly from the Bann to any individual of the garrison of Ascension:”* and indeed it appears that the first person attacked with the characteristic symptoms was not one of those known to have been in the ship or in contact with the sick, but a boy, on the 11th of May, respecting whom “it is neither known nor believed that he had any nearer communication with the sick of the Bann than passing daily at no great distance from the tents to feed his father’s poultry, and he was never on board that ship.”† The tents here alluded to were, as pointed out by Sir William at page 5, occupied as an hospital for the accommodation of the sick from the Bann immediately on her arrival, and were situated at about five hundred yards from the garrison, and *all intercourse was interdicted*. He informs us that up to this time the restrictions on the intercourse between the ship and the garrison had not been much attended to, several individuals having been on board after the landing of the sick; but that from the time of the boy’s illness “every proper precaution was taken for preventing the extension of the disease to the outposts; notwithstanding which, six men, two women, and seven children were taken ill at Springs, but fortunately none at the Green Mountain, though one of the men belonging to that post had been on board the Bann at the sale before mentioned.” We shall only add that the surgeon of the Bann, “an excellent and intelligent officer,” ascribed the disease to the long stay of the ship in port at Sierra Leone, where the crew had been much exposed to the sun’s rays in re-fitting her rigging, &c.; and that when this vessel had been, in 1821, on the Jamaica station, a fever, with yellow skin and black vomit in some of the cases, appeared among a party of forty men, put on board for a passage, who had suffered imprisonment with hard labour at Panama for four months;‡ which disease, according to the surgeon’s journal, did not extend to the crew, nor could he “trace a single instance of disease to contagion,” although “the smallness of the vessel, and other circumstances, would not admit of a separation between the sick and ship’s crew.”

That there were, on a *prima facie* view of the irruption of the fever in Ascension, reasonable grounds for suspecting the agency of contagion, there cannot be a doubt; but, as may now be seen, it is far from being established by anything like legitimate induction from evidence, that the one was the cause of the other; and, added to all that is now known upon the subject of yellow fever, many will probably join with us in believing that, admitting the transmission of this disease from individuals in this instance, would be illogical and nothing short of admitting that to be *vrai* which is shown to be only *vraisemblable*.

We shall close this essay by referring to some of the facts bearing on the subject of contagion, as they occurred during the yel-

low-fever epidemic at Gibraltar in 1828,* when it fell to our lot to observe its rise, progress, and termination. For minute details, full of interest, we can confidently refer to what has since been published by the following gentlemen of unquestionable veracity:—Mr. Wilson,† attached for many years to the duties of the Civil Hospital at Gibraltar; Mr. Hugh Fraser,‡ in charge of the Civil Hospital for some years, having previously served there in the 12th regiment; Mr. Amiel,§ now surgeon to the 12th regiment, a gentleman who has been for more than thirty years in His Majesty’s service, and had witnessed the disease at Gibraltar in the former years specified, as well as sporadically on other occasions; Dr. Smith,|| surgeon to the 23d regiment; and Dr. Chervin,¶ one of the members of the medical commission which arrived at Gibraltar from Paris towards the close of the epidemic of 1828. Besides these, the French government has published a series of documents furnished by the medical commission, to which is appended, on the part of one of them (Dr. Chervin), a declaration that statements of some consequence, afterwards shown to have been erroneous, had obtained a place in the collection.

After having paid the utmost attention to every point connected with the first appearance and progress of the epidemic in question, it would be an utter dereliction of our duty towards the public, to attempt, under the guise of extreme candour, to cast unwarrantable doubts on the many important statements made by the gentlemen whose names are above given, in proof of the disease not having been imported, and of its not having, under any circumstances, been communicated from person to person: we are enabled, on the contrary, to declare that most of the important facts cited by those gentlemen in proof of non-contagion, were verified under our own observation while on the spot. A reference to some of the publications pointed out in the notes will show how individuals have been

* Here, as matter for future reference, a view of the mortality from yellow fever at Gibraltar is given for five years in which the disease appeared there to a remarkable extent, from 1804 inclusive.

publicly denounced to the world as having garbled and distorted circumstances in a manner which must for ever hold them up to the indignation and contempt of the profession at large. Indeed we cannot but regret that usage will not permit, on an occasion like this, an exposure of the conduct of interested persons, whose foul labours were directed to pervert truth on a question upon which, for generations to come, the lives of thousands must depend, and for which they so well merit exposure and punishment.

At the commencement of the epidemic there were very few medical men in the garrison who could be called anti-contagionists. Conceiving that our then medical chief, the late Dr. Hennen, was disposed to make up his mind too soon against importation and contagion, some of us* wrote to him, indeed, confidentially, requesting that he would give further attention to the reports regarding the importation of the disease by a Swedish ship from the Havannah, called the Dygden; but an impartial consideration of all the facts which passed in evidence before us subsequently, left no doubts in our mind as to the cause, though mysterious in its essence, being of a strictly local nature. At the strangely-constituted board appointed at Gibraltar to enquire into the origin of the disease, and at which, to the astonishment of all who had read the works of Bancroft and Burnett, the present superintendent of quarantine in England was named president, much passed over which a veil must be drawn here; and we shall only place on record the full opinions of two of the members, they being certainly most entitled to weight with the public. Mr. Judge Howell says, "Upon a careful review of all the proceedings before this board, I am of opinion that the evidence brought forward has totally failed to prove that the late epidemic disease was introduced from any foreign source, either by the Swedish ship Dygden or by any other means; and I am further of opinion that the late epidemic had its origin in Gibraltar." Colonel Chapman, (now Major-General Sir Stephen Chapman, Governor of Bermuda) says, "Judging from the evidence produced before the board, the manner in which it has been given, together with the description of persons who have been brought forward as witnesses, I am decidedly of opinion that the late epidemic disease is of local origin. As to the importation of the late epidemic, I am of opinion that the attempts to prove the introduction of the disease, after months of previous inquiry, by those who wished to prove it, have totally failed." The latter part of this needs, we presume, no illustration. Three voices, including that of the president, were in favour of the importation of the disease; according to another member, it might have been from foreign and local causes conjoined; while the seventh (the captain of the port) declined, through delicacy, re-

cording an opinion.* On the above occasion the examinations of some of the medical gentlemen attached to the army were most imperfect, *the progress of the disease among the men under their charge not having been entered into; and several of them were not examined at all!*

That a local cause of yellow fever, unconnected with persons, was in operation through a certain space at Gibraltar, in the latter months of 1828, was amply demonstrated in every possible way in which such a point could be proved. To some of the most striking occurrences bearing on the subject we shall here revert, leaving, for want of space, many valuable details, as they have been furnished by the several gentlemen formerly referred to. The failure of proof as to the importation of the disease has been admitted by the army medical board in England, to whom a copy of all the proceedings of the Gibraltar commission was sent for examination. It was shown that the disease made its appearance exactly about the same time of year as on all preceding epidemics at Gibraltar and other parts of Spain;† and that, as on all former occasions, the morbid influence was limited to the western face of the rock, and to a small village (occupied by fishermen and by a small military post) situated at the base of the rock, on its eastern side. On the sandy plain called neutral ground, several thousand of the civil population, as well as three regiments of infantry and some sappers, were placed under canvas or in huts, soon after the epidemic made its appearance: on two plateaux, situated at different elevations on the southern extremity of the rock,‡ three other regiments, with a detachment of artillery, were also encamped. Although very great intercourse subsisted during several weeks between the places where the disease prevailed and the three points here specified; and though, up to the appearance of the last case, there were no measures in force which could be considered efficient in a disease avowedly contagious,—for medical men fresh from their full wards were daily in contact with the healthy persons in the camps,—still the disease did not attack the persons on the neutral ground, or on the plateaux, unless duty or occupation obliged them to pass certain limits, and respire, for a longer or shorter time, the atmosphere of particular localities—the part of the town itself, called the 24th district, being the most dangerous of any. If any cases had their origin beyond the points spoken of, they must have been very few in number, as among our army

* To show the facility, at any time, of falling into the error of assigning, as a cause of the Gibraltar fever, that which may be only a coincidence, the above gentleman laid before the board a document shewing that between 1814 and 1820, *eight hundred and forty-four ships had entered there from different countries where the disease is known to prevail.*

† The first cases usually appear in August, though *avant-coureurs* have been not unfrequently observed in July. On one occasion only, as far as we are aware of, has an epidemic appeared earlier in Spain—that at Malaga in 1804, which broke out in June.

‡ Windmill-hill and Europa-flats.

* Dr. Smith, 23d regiment, and the writer of this, surgeon at the time to the 43d Regiment: the letters here referred to were found in Dr. Hennen's office after his death.

medical friends at Gibraltar, by whom the point had been frequently discussed with us after the epidemic, scarcely a single well-authenticated case could be made out, among the military or their families, where an attack had taken place among those who had not entered the regions of malaria.*

The following facts have been placed on record relative to this epidemic; it will be perceived how far they are calculated to set at rest a question of prodigious importance to a great portion of mankind. With scarcely any exceptions, security from attacks was obtained by the military and civil part of the population at the three points of encampment mentioned, as well as on board of ships lying in the bay, to which many of the latter fled. It was shewn that, though many individuals who had been in close contact with the sick in the town, &c. had removed to camp, taking with them their bedding and some furniture, no spreading of the disease in the camps or huts took place. Up to about the 20th of October, the convalescents underwent no process of purification previous to their being sent from hospital to their respective camps. By reference to Mr. Hugh Fraser's papers it will be seen that this gentleman, who was surgeon to the civil hospital, had, for want of room, been obliged to discharge a great number of persons from that establishment before their convalescence had been well established,—some indeed with hemorrhage still from their mouths,—that several of these people took with them articles of bedding to the small tents and huts in which their relatives resided, without the disease having been transmitted to the latter. By Mr. Amiel we are shewn that his regiment (the 12th) became soon free from cases after they encamped on the neutral ground, a few only having occurred among men who may be supposed to have carried out the seeds of the disease in their systems;—that so long as this regiment sent no men into town on duty, no attacks took place; but when the town duty was resumed, cases again occurred, and exclusively among those men who had been so employed. He gives us the important fact, that “ninety-two women of that regiment, and one hundred and ninety children, who never were allowed to repass Bay-side barrier, continued perfectly healthy; and one woman only, (the armourer's wife) who, during the period, obtained leave to enter and stay a few days in the garrison, caught the fever and died of it. Several of these women passed the night in the same beds with their husbands, attacked with and labouring under the epidemic fever; and, besides, continued, as well as their numerous children, to use the same bedding, after the men had been removed to hospital; but in no instance was the disease contracted by the wife or the children after that full exposure.” Were we to point out one situation more calculated

than another to favour the transmission of a disease by personal contact, it would be that of several individuals living in the small space of a tent or hut; yet we see that, put to this test, there was no transmission. Dr. Smith, in his paper referred to, shews that in the 23d regiment, the disease, notwithstanding exposure to direct or indirect contact with the sick, was also confined to those who had been within certain bounds; and he exposes fallacies in certain statements relative to people on board vessels in the bay, whose safety, we can join him in averring, did not arise from their having been cut off from communication with persons or things from the town. In a regiment, (43d,) of which we had, on the occasion in question, the medical charge, we can aver that on summing up all the occurrences, the following clearly appeared:—that although our regular hospital servants had been greatly harassed at an early period of the epidemic by attendance on yellow-fever patients, none of them were attacked until nearly one month after the admission of the first case; not, indeed, until the disease had attacked individuals who were not employed in attendance on the sick, but lived on that part of the rock where the hospital* is situated;—that, in the course of the first month of the epidemic, a party of temporary attendants, consisting of from two to four, or more, was sent daily from a remote barrack or camp to do duty in the wards of the hospital for twenty-four hours; their employment absolutely comprised whatever can be conceived of the most assiduous nursing during the night as well as by day; and the result, according to an investigation made afterwards, was, that, in the first place, no greater proportion of the sixty-nine men (the total number so employed) had been attacked, than of the whole mass of the regiment which had not been on this service about the sick; and that, in the next place, any of them who happened to be attacked within a period of several weeks after, were ascertained to have been on duty (guards, &c.) within the points where the atmosphere was most deteriorated. Here, then, we have, in a manner, an *experimentum crucis*, on such a scale as cannot be denied to give it the highest importance in the eyes of the profession. We took the precaution to have the names of these sixty-nine men, together with other particulars, duly registered and verified by the adjutant of the regiment, in a document forwarded to the office of the colonial secretary in London. The next remarkable fact regarding attendants on the sick was, that of several medical men (six or seven of whom had but lately arrived at Gibraltar) employed at an hospital on Windmill-hill, and at another in a low situation near the neutral ground, not one suffered from the disease: the same immunity was extended to the servants employed at those points, among whom were some who, not having passed

* At one time the writer of this essay, not aware that this was found to have been so generally the case, gave it as his opinion officially, that the morbid principle might, during epidemics, occasionally affect persons a few hundred yards beyond the rock.

* A fine building, calculated for the accommodation, under ordinary circumstances, of the sick of five or six regiments,—situated at an elevation of one hundred feet on the S. W. part of the rock, near the entrance of the bay.

through former attacks, could not be said to have escaped on that account. We took great pains to procure the names of the women who washed for the sick of the army during the epidemic, and it can be confidently stated that the result of inquiry, as to the numbers attacked, was quite in opposition to the doctrine of the disease being communicated indirectly by means of articles of dress, &c. Another point to be considered is, whether immunity from attacks took place where pains had been taken to exclude all communication, direct and indirect, with the sick. At the dock-yard this did not, in 1828, prevent individuals from being attacked; neither did prisoners confined in solitary cells at the "Moorish Castle," situated within the walls of the town, escape attacks. We are aware, too, that among the private families on the western face of the rock, who took precaution by seclusion, cases also occurred. On the neutral ground, on Windmill-hill, on Europa-flats, as well as in ships in the bay, persons who thought proper to adopt precautions may be said to have escaped; but the same, we are quite sure, may be said of those who, *living there*, adopted no such precaution as shutting themselves up. The only step holding out security at Gibraltar or any where else, as is now so generally understood every where, and as had been practised many years ago in some parts of Spain, is to remove quickly from the malaria points; and this, according to all experience, would seem a measure eminently entitled to the appellation of *sanitary*.

The foregoing materials, drawn from sources so varied, will probably aid the profession at large in forming an opinion upon a long-agitated question.

(J. Gillkrest.)

FRAMBÆSIA.—See YAWS.

FUMIGATION.—See DISINFECTION.

FUNGUS HÆMATODES, (from *fungus*, a mushroom, and *αἱματώδης*, bloody;) a term proposed by Mr. Hey, of Leeds, in his work entitled "Practical Observations in Surgery," published in 1803; to distinguish the particular form of disease now about to be discussed, from cancer, an appellation under which writers, both ancient and modern, until the commencement of the present century, seem to have included every variety of ulcerative tumour which proved untractable in progress and malignant in nature. Unhappily these are features too characteristic of fungus hæmatodes to have eluded the general denomination; but the peculiarity of appearances thus designated must in all ages have attracted notice, and in the records of various writers it is impossible not to perceive that examples of what we now call fungus hæmatodes have been regarded as extraordinary cases of cancer, or instances of anomalous disease.

At the period when Mr. Hey suggested the consideration of fungus hæmatodes as a distinct disease, it appears that the observations of Mr. John Burns, published in his valuable work on Inflammation, in 1800, were unknown to him.

Mr. Burns treated of it under the title of *spongoid inflammation*. From Mr. Abernethy, in his classification of tumours, (Surgical Observations,) it has received the name of *medullary sarcoma*, since called by the French pathologists *tumeur encephaloïde, cerebriforme, carcinome sanglante, cancer mou*. Dr. Young has ranged it, in his system of nosology, as one of the two species of the genus carcinoma, viz. *C. spongiosum*; applying the term *C. scirrhosum* to that form of hard tumour which is characteristic of the disease commonly called cancer.

The appearances of the fungus hæmatodes, the circumstances attending its origin and progress in the human body, and the purposes of practical medicine, demand and fully justify its separate consideration. That our view, however, of the distinctive differences between it and cancer may be the more clear, we propose, in the first place, to shew the analogy of the two diseases, and by which they seem to have been confounded, avoiding altogether as useless any subtle disquisition on the subject of their original identity, which the present state of pathological knowledge does not entitle us even to discuss.

They are both apt to be manifested in persons apparently of the same temperament; to be evinced by the formation of a tumour in the same regions of the body; often to be traced to similar exciting causes; and in each often to arise spontaneously; to be prone to ulceration, and afterwards to discharge matter not purulent in its nature; both often bleeding profusely: cancer sometimes, like fungus hæmatodes, produces a fungous excrescence; and both generally alike contaminate the absorbent system: both are destructive of the neighbouring parts, of whatever nature the structure of such parts may be, and frequently affect several organs at the same time; both, also, it must be acknowledged, are most frequently untractable and destructive of life.

The history of fungus hæmatodes to the period we have mentioned of its separate consideration, must, it is obvious, be involved in that of cancer; but it is impossible at the present time to trace back the observations proper to this form of disease, with such a degree of accuracy as to assist us in its elucidation. The difficulty of defining fungus hæmatodes, like that of defining many other diseases, consists in the variability of its symptoms in its progress; and, therefore, to the recorded histories of it we must refer for that information which is essential to its being well understood. The part, too, in which it is developed, the state of the constitution, and the age of the individual, are so many other causes of variety in its appearance. But the advantages of a concise definition are too obvious to deter us from hazarding such a one as we conceive to be consistent with the circumstances of the disease, and the present state of our knowledge regarding it. We characterize it then as a morbid condition of the body, evinced by the development of an elastic uneven tumour, or tumours, not painful in their early stage, and

becoming so only by implication with surrounding parts; tending to ulceration, and by ulceration presenting to view a soft and spongy fungus, rapid in its growth, readily bleeding in vascular textures, and emitting a peculiar serous discharge of a very fetid odour, more or less coloured with blood.

A blow or injury of some kind is very often the immediate forerunner of this species of tumour, and the latter generally leads to the first manifestation of the disease; but in many instances its origin cannot be traced to any particular exciting cause. It is found to occur much more frequently in the young than in persons advanced in life; children from the earliest age being often its victims. The persons whom it has most generally attacked have been those of a sallow complexion, a lax and flabby texture of the skin, and a weak circulation. Observations are wanting to enable us to decide whether it is more prone to manifest itself in one sex than in the other, although the last mentioned observations, with the recorded experience of this and cancerous diseases, are favourable to the supposition that females are more frequently the subjects of it than males. Climate, it is probable, has some influence on its production; for we are told by Sir Everard Home, in his Dissertation on Tumours, that in the island of Otaheite, and those of its neighbourhood, where fighting is the common mode of deciding quarrels amongst the women, the blows are principally aimed at the breast, which has no defence, and that cancer has never been met with in these countries. We have good authority, too, for stating that it very rarely arises in India; and these remarks, for obvious reasons, we conceive to be equally applicable to the form of disease which is the subject of this article. That the constitution favourable to the development of fungus hæmatodes is transmitted hereditarily we cannot doubt; and that all circumstances which are of a debilitating nature have a secret influence in preparing the way for its production, we conceive may reasonably be assumed from the accumulated experience and observation of past ages on the predisposing causes of cancer. In a large majority of instances, fungus hæmatodes has terminated fatally: indeed, the recorded exceptions are so rare, and pathologists of the highest repute so agree in opinion as to its general fatality, that it may almost be questioned whether the instances which are related of its favourable issue are not to be referred to some distinctive peculiarity in the morbid change, unrecognizable in the present state of science, rather than to any favourable state of constitution or difference of treatment. The period to which life has been limited after the development of this terrible disease has rarely exceeded two years, whether its removal has been attempted by extirpation of the tumour, or every other expedient adopted consistent with the circumstances of the case and the resources of science. It generally proves fatal in a much shorter space of time, and death too often seems to have been expedited by the removal of the local disease, even

to the extent of extirpation of the part, or amputation of the limb on which it may have been situated. In those cases in which the eye has been extirpated, unless a return of the disease has produced death, the growth of a similar tumour in the brain has usually been the immediate occasion of it; and when a limb, or the mamma has been removed, or even the testis, a corresponding formation in the lungs has immediately followed, and, increasing with rapid strides, has put a fatal period to the sufferings of the individual; whilst at the same time the liver most commonly, and generally several other organs and structures of the body, have been studded with similar formations.

The physical circumstances leading to the formation of these tumours are connected with a most important subject of pathological science, viz. the local and constitutional origin of disease. After premising that pathologists of the highest repute in this country have assigned to fungus hæmatodes a local origin, it is with the utmost deference we venture to assert that proofs are wanting to establish this fact, and that we consider it infinitely more consistent with acknowledged physiological principles, and the changes which we know to be produced in the elementary components of the body in this as well as in some other diseases, to assume that a morbid condition of the blood is a link in the chain of causes of fungus hæmatodes, prior to its local manifestation. We should scarcely have hazarded this opinion had we not met with sanction in the observations of Bichat and Andral; and but for the fact, admitted by those who have contended for its local origin, that the secondary formation is consequent to that change in the constitution which appears to us to be productive of the original tumour.

No one will doubt that the blood, like the other constituents of the body, is frequently altered in its nature by disease; and as it is secondary only to the chyle in the sequence of bodily formations, and is the acknowledged element of all secretions healthy and morbid, the question, we conceive, resolves itself into either the presence of the morbid matter being already in the blood, or a specific adaptation of the secreting organ to its formation. For proof of the latter we have searched in vain; but with regard to the former, we know that the qualities of the blood when this disease exists are changed; that it is much thinner than healthy blood; difficultly, if at all, coagulable; and almost wholly unequal to the process of adhesive inflammation; in fact materially deficient in the important constituent, fibrin. Andral has discovered in the blood not only different elements of secreted fluids, but, as well as other morbid productions, the peculiar one which belongs to this disease so combined with it as to alter its physical properties; occasionally limited to particular vessels, but sometimes in the greatest part of the circulatory system, when at the same time a corresponding morbid production was seen to pervade the texture of many of the solids. Similar facts, he observes, have been mentioned by Béclard and Velpeau;

the former having referred to a case in which the heart and the principal trunks of the vessels were filled with a solid clot, the interior of which presented numerous collections of encephaloid matter; and the latter to a similar formation in the vena cava. He also cites the case of a man who died almost suddenly, after having shewn some symptoms of cerebral congestion, and in whom, upon examination, there was found through the whole extent of the circulatory system a blood of a pultaceous consistence and blackish red colour, resembling the matter of certain abscesses of the liver. For further information on this part of our subject we refer to the interesting observations of Andral on the lesions of the blood; but we must acknowledge that there are still wanting many facts to remove all the objections which may be opposed to our views.

It is universally admitted that fungus hæmatodes is in most instances a constitutional disease before it comes under medical cognizance, and its origin is usually referred to a "peculiarity of constitution;" an observation which to us seems almost to involve the question at issue. That the local effect is, as in the case of other tumours, a morbid secretion, is undoubted. From its consistency it readily insinuates itself in the interstitial cellular substance, separating the vasa vasorum from their natural attachments, and by constantly exposing the external parietes to the action of a semifluid, they may besaid to undergo a kind of maceration, and hence so to degenerate as to become unequal to the retention of their contents, or readily lacerable by the slightest local injury. Thus we consider the hemorrhagic tendency to be secondary, and superadded to the secretion itself; an opinion which we conceive to be verified by the appearance of the tumour, as seen in a state of ulceration in the mamma or extremities; as modified when it occurs in the glandular structure of the testicle; or as inspected when separated from the body and carefully washed with water.

The substance of the tumour, which from its resemblance to the brain has been called cerebriiform and encephaloid, presents itself, according to the observations of Laennec,* under three different forms: 1. encysted; 2. irregularly compacted without cysts; 3. infiltrated in the tissue of an organ. In whichever of these states it exists, its progress may be divided, says this eminent pathologist, into three stages; that of its formation, or the stage of crudity; that of its entire development, when it most resembles the brain; and that of its *ramollissement* or softening. It has been remarked, however, by Andral, that we have no proof that the encephaloid matter in the state of softening can only occur subsequently to the other stages; and we are disposed to believe with him that this is in many instances the state of its primary formation,—the state certainly in which it is first recognized as characteristic of the specific disease.

In its earliest stage the cerebriiform tumour is lobular, moderately consistent, and appears composed of minutelobules closely compacted, marked by lines running parallel but not cooping with each other. Its colour is a dull or yellowish white. The cyst is probably secondary in formation to the enclosed substance, as traces of cyst are often found in one part and the tumour exposed in another. When completely developed, it is homogeneous, in colour milky white, occasionally tinged with red, and in consistence resembling the brain; it is greasy to the touch, and when divided soils the knife; when cut into small slices, it is semi-transparent; like brain also, when exposed to the atmosphere, it softens; and when the softer parts of the tumour are washed away, or when the mass is compressed, a loose filamentous texture, resembling cellular membrane, remains. In the mass, however, as separated from the body, a number of bloodvessels are usually to be observed pervading the whole texture. Their parietes are thin and easily ruptured; and extravasated clots of blood are here and there interspersed, giving the whole, says Laennec, an appearance resembling the lesions observable in dissections of sanguineous apoplexy.

The cerebriiform matter does not remain long in the state described, but proceeds rapidly to that of *ramollissement*, and, thus rendered more miscible with the extravasated blood, its colour is influenced accordingly, and is varied from a reddish white to a dark sanguineous hue. This state of softening is found to occur at different periods in the same tumour; some parts being much firmer than custard, and others harder than the most solid parts of the healthy brain. This medullary matter is very sparingly soluble in water: if exposed to the flame of a candle in a silver spoon, it assumes the colour of opal, and it leaves after evaporation an inappreciable residue. With the addition of spirits of wine the watery solution threads slightly, without coagulating by the action of heat; this mixture evaporated, like the preceding, leaves some small grey clots. Exposed to the direct action of heat, it becomes brown, but does not liquify like grease; and it has a smell of roasted meat. If immersed in spirits of wine, it does not undergo any apparent change. In a saturated solution of corrosive sublimate it coagulates so as to form white filament, the solution remaining transparent. Acetic acid has no visible effect upon it. Slowly boiled in water the liquid remains clear, without grease; and does not jelly when it becomes cold.*

The medullary structure, though often found alone, frequently co-exists with other varieties of diseased production; as fibrous or scirrhous masses, pus, scrofulous matter, melanosis, hydatids,† and in some cases ossific or earthy particles have been found intermingled with the pulpy matter. In many hæmatoid tumours there are distinctly insulated portions much resembling boiled yolk of egg; and so often

has this peculiar substance been found in those organs wherein fungus hæmatodes has been detected, that the circumstance might almost be considered a characteristic of the disease.

We have stated that the earliest notice we have of fungus hæmatodes as a distinct disease has been transmitted to us by Mr. Burns, under the name of spongoid inflammation. The cases related by him, five in number, were confined to its occurrence in the extremities. Of the ten cases next published by Mr. Hey, it manifested itself in five in the extremities, in three in the female breast, in one in the lower jaw, and in another at the back of the neck. Mr. Abernethy, in his *Surgical Observations* published in 1804, related a case of diseased testicle, to which he gave the name of medullary sarcoma, since used by him and by many surgeons synonymously with fungus hæmatodes as it occurs in this as well as in other parts of the body, and the identity of which with the pulpy testicle described by Dr. Baillie is now universally admitted. In the best treatise we possess on this subject, published by Mr. Wardrop in 1809, and to which we are largely indebted, are collected all the scattered accounts which our literature affords relating to fungus hæmatodes prior to that period; and there we find related cases with dissections of it as it occurs in the eye, the uterus, the ovaria, the liver, the pancreas, the spleen, and the lungs. Hæmatoid tumours have since been met with, as the same writer remarks,* in the urinary bladder and alimentary canal, in the brain, in the bones, in the mesentery, in the omentum, and in the thyroid gland. Laennec states that he has seen two cases of encephaloid growth in the heart: in one the morbid matter formed several small masses in the muscular substance of the ventricles; in the other it was deposited in layers from one to four lines thick along the coronary vessels. M. Olivier, in his work on the spinal marrow, relates another case of encephaloid tumours deposited in the substance of the same organ. M. Velpeau has published a remarkable case of the same kind, in which similar tumours were also found in the lungs, between the pleura and ribs, in the bronchial glands, under the mucous membrane of the stomach, in the duodenum, in the pancreas, in the right kidney, in the liver to the amount of several hundreds, between the tunics of the gall-bladder, in the different parts of the peritoneum, in the thyroid gland under the skin, and in the muscles of the right thigh. We ourselves remember to have witnessed a case in St. George's Hospital, which proved fatal, and on a post-mortem examination exhibited the existence of the same kind of tumours, in very considerable numbers, in all the organs of the several cavities of the body, and dispersed under the integuments of the trunk, as well as of the superior and inferior extremities. The absorbent glands, though in most instances contaminated in the early or in

the advanced stages of the primary tumour, as far as we know, have never been the original seat of the disease. In some cases they grow to an enormous size, whilst in others they are but slightly enlarged. In some the primary affection makes little progress, whilst the disease of the glands advances rapidly and seems to be the immediate cause of death. Their structure is generally converted into a substance resembling the primary tumour, exhibiting a homogeneous pulpy mass contained in one firm cellular capsule; in this respect differing from the primary tumour, which is usually lobulated and intersected by cellular strata. In some cases the skin covering the gland ulcerates, and forms a foul sloughy ulcer, but rarely, if ever, produces a fungus.*

The indiscriminate manner in which cancer and fungus hæmatodes have been usually regarded, renders it necessary that their diagnostic symptoms should be particularly attended to; we shall now proceed to an exposition of these in their general character, reserving for after consideration their local peculiarities.

The fungoid tumour before ulceration is soft and elastic, giving in most cases a more or less obscure sense of fluctuation. It does not always occasion pain; and when it does, it is of a throbbing, and not lancinating kind. It exists very rarely beyond two years without going through all its stages, and occurs most frequently in persons who have not reached the middle period of life; very often in childhood and from the earliest infancy.

Immediately after ulceration has taken place a soft spongy fungus appears, and grows rapidly; emitting a discharge like serum, which immediately mixes with the blood, always to a certain extent at the same time extravasated. The appearances of the fungus hæmatodes when taken from the body having been already discussed, we need only suggest a comparison between its properties and those of a cancerous tumour. The cancerous, or, as commonly called, scirrhus tumour is hard, firm, and incompressible, and in its formation and progress is always attended with lancinating pains; the integuments above the tumour are usually corrugated, and exhibit on their surface several short white lines, which are in reality so many germs of the disease. In many instances scirrhus is slow in going on to ulceration; it often continues for many years, or until the termination of life, without it. It occurs generally in persons advanced beyond the middle period of life, and is scarcely ever known to take place before the age of twenty-five. In its ulcerated state its hard firm substance is transformed into a thin ichor; and, generally, the tumour does not increase in bulk, but is destroyed by the process; or if a fungus succeeds, it is hard and firm in its texture. The scirrhus tumour, when separated from the body, is hard, firm, and incompressible, and is composed of two substances, one indurated and fibrous, the other soft and inorganic. The

* Preface to Baillie's *Morbid Anatomy*, edited by J. Wardrop, Esq.

* See Mr. Wardrop's *Essay*.

fibrous matter is the most abundant, consisting of septa, which are paler than the soft substance between them. The latter is semi-transparent, of a bluish colour, resembling in consistence softened glue, but occasionally more opaque, softer, and somewhat oleaginous. The fibrous matter is more or less condensed and radiated, the interstices being filled with the softer substance; and sometimes the whole tumour, or parts of it, are converted into a substance resembling cartilage, which is occasionally the nidus of bony depositions.

Scrofulous tumours bear a much nearer resemblance to those of fungus hæmatodes previous to ulceration than the preceding. Their locality is often the same, though the lymphatic glands are most frequently the seat of the primary tumour in scrofula,—an occurrence which is rarely, if ever, found in fungus hæmatodes. As the tumour of the former approaches to ulceration, the integuments assume a red, but never the livid colour of the latter, and when pressed are considerably less elastic; they are frequently also found in clusters, which never is the case in fungus hæmatodes. The sallow, almost greenish cast, in the complexion of the sufferer from fungus hæmatodes, and the smooth and fair skin of the scrofulous individual, will materially assist in determining the two diseases. After ulceration has taken place, all difficulty is at end; the bloody fungus, and peculiar fetid discharge of the one, compared with the flaky pus-like matter of the other, with the whole character of the ulcers, and their progress, render it unnecessary to dwell on the distinctive peculiarities of the two diseases. When the brain, or viscera of the cavities belonging to the trunk of the body, become the primary seats of the fungus hæmatodes tumour, the indications of its existence are necessarily very obscure. In its early stage, either when external or internal, the tumour is often wholly unirritant; and the presence of formidable disease is suspected only from the unhealthy aspect of the countenance, produced by the peculiar sallow complexion of the skin. The tumour, as it increases, will of course produce all the mechanical effects of a foreign body, in whatever part it may be situated; and the influence of disease will be more and more manifested throughout the system. Increasing debility, and at length hectic fever, are the prominent constitutional effects which we are called upon to combat; but experience shews that we have yet to learn the means of staying, even for a little time, their rapid progress to a fatal termination.

When there is already evidence of the existence of fungus hæmatodes by its appearance in an external part, and symptoms of disease in an internal organ arise, we cannot fail in deciding its nature. Of those organs which have no outlet, the liver is the only one in which we can by external examination ascertain its presence. Dr. Baillie, however, states that he has only known it as a secondary formation in this organ, and Mr. Wardrop's observations are to the same effect; but the

latter writer suggests that the soft brown tubercles of the liver, described by Dr. Baillie, are probably of this nature, though they are merely noticed as a very rare appearance of disease, without any remark as to their identity. In Dr. Farre's work on the morbid anatomy of the liver, we find described a disease of this organ named by him *tubera diffusa*, the character of which bears so close a resemblance to that of fungus hæmatodes in other parts, that with due allowance for the modifying influence of the organ itself, we are inclined to consider it as the same. In this as in other organs, it has usually proved irremediable, and admits only of a palliative plan of treatment: every attempt to cure or suspend its progress by the specific action of mercury has proved worse than useless, an observation applicable to the treatment of fungus hæmatodes wherever may be its locality; for it tends only to expedite the exhaustion of those powers which are rapidly failing in defiance of all the means which art can yet summon to their support.

To complete the view of fungus hæmatodes, considered as a disease generally, we ought now to give an account of it as it affects the various internal and external parts of the body, and more particularly those in which it exhibits characteristic appearances, as the uterus and its appendages, the eye, mamma, testis, and extremities; but as nearly all these are within the domain of surgery, and come not therefore into the plan of the present work, we must here terminate what we had to say of the pathology of the disease.

Treatment.—Having had frequent occasion throughout the present article to advert to the untractable nature of the local and constitutional symptoms of the disease which is its subject, it might, on a superficial view, appear superfluous to make any further observations on its treatment. Those, however, who are in search of information to be adapted to circumstances, will be the more anxious for it in proportion to their difficulty, and it is as important in practical medicine not to make attempts inconsistent with reason and experience in incurable cases of disease, as to use the requisite means in those which are curable. It is of the utmost importance also, in our views of improvement, to know what has been done, in order that we may learn what more we can do,—or, as Andral has emphatically expressed himself on a subject yet in obscurity, and not irrelevant to the present, to keep an inventory of the facts we are in possession of, and to determine accurately where we are, in order that we may know where we are going.

It is to be kept in mind that fungus hæmatodes is a disease which, from the earliest period that it comes under professional attendance, evinces manifestations of increasing and hitherto irresistible debility; and that, as a morbid poison, which it is in the strictest sense of the term, its action is progressively destructive of that organic irritability which belongs to a healthy condition of the solids.

These, it must be confessed, are rather negative than positive indications to our treatment; but, for the reason suggested, they are not the less essential. Whether we regard the local or constitutional symptoms, reason as well as experience have determined that the class of remedies which constitute the antiphlogistic system is to be excluded from our plan of treatment. Locally considered, frictions, plasters, leeching, blistering, or handling this species of tumour, have been found rather to accelerate than to retard its progress. From its contiguity to particular structures it occasionally excites an irritative heat, which the simple application of tepid water, or at most an evaporating lotion, consisting of one ounce of spirits of wine with five ounces of common distilled or rose water, is calculated to remove. The use of a lancet, or other incision, with a view of evacuating its contents, under the mistaken idea of the tumour being in reality an abscess, (a mistake which has unfortunately frequently occurred,) has always tended to accelerate the progress of the disease, and is calculated to bring great opprobrium upon the operator. When ulceration takes place and the fungus appears, it is important to know that the direct application of greasy or unctuous substances seems to increase, and only when combined with an escharotic, to retard the vegetative tendency. A painful or irritable state of the fungus has occasionally been relieved by an application of three drachms of the subnitrate of bismuth, mixed with one ounce of spermacetic ointment; and in such a condition fomentations with a decoction of the heads of papaver somniferum, or the fresh leaves of the conium maculatum, may be resorted to with advantage. But for the most part we have to contend with a fungous growth which is insensible, and seems to indicate the use of direct stimulants; the strongest escharotics have therefore been applied, and in some instances without checking even its increase. Mr. Hey informs us that neither the hydrargyrus nitratu ruber, the hydrargyrus muriatus, the antimonium muriatum, nor the undiluted sulphuric acid, have been sufficient for this purpose; but as we frequently find that the upper and exterior part of the fungus is separated and falls away, by the exuberance apparently of its vegetative principle, we cannot reasonably expect much advantage from such applications, or ought to do so only in the ratio of our approximation to the base of the tumour. Our belief is, that this is placed beyond the reach of surgery, and, failing in our attempt, that such means have the effect of accelerating the fatal issue of the disease.

We have seen apparently some temporary advantage, in two instances of this affection in the female breast, from the direct application to the ulcerated surface of a paste made of carbonate of iron, with a sufficient quantity of honey to give it a soft consistence; but neither in this nor in any other commonly used applications have we any promise of a positive remedy. Whether the application of a solution of the chloride of lime may be advan-

tageous, our experience in this affection does not enable us to determine; but from our knowledge of the relief and comfort it has produced as an injection in cancerous affections of the uterus, and as a lotion to foul ulcers, we cannot refrain, in the dearth of our resources, from suggesting its use. We anticipate no more from it than the advantage to which we are at present limited, of promoting the comfort of the sufferer; and, in his catalogue of miseries, the horrible fetor of the fungus, which it is calculated to remove, is certainly not the least distressing.

We have already sufficiently expressed ourselves on the question of excision and amputation; it remains for us only, therefore, to consider the constitutional treatment. We have searched in vain for authority to assist us in this part of our subject, and cannot but feel daunted in offering our own suggestions when one of the most experienced surgeons of the present day* has thus expressed himself: "We may sometimes prevent the disposition to the formation of this disease by giving alterative medicines; but no medicine with which we are acquainted has any power over it when it is once formed." So far as it is connected with the even less fatal disease, cancer, which, though mostly incurable, has its hundred remedies, we may fairly take the sanction of the remark, "*tædet et pudet garrire de remediis specificis.*" We have still, in the exercise of our profession, to do the best that circumstances may allow; and it is to be remembered that we are as much the guide, and our duty is as important in the difficult and dangerous path, as in that which is plain and easy. The indications we possess would lead us to advise the use of a diet nutritious, calculated to increase the fibrinous quality of the blood, and at the same time easy of digestion; the powers of the stomach being alike enfeebled with those of the other organs of the body. We should also recommend free communication with the external air, and gentle exercise, as long as they can conveniently be borne; the occasional use of medicine calculated to keep up the natural action of the alvine canal without exhausting the bodily powers, and such tonics as we have found in this and diseases most nearly allied to it to preserve the patient longest, and with least tendency to disturbance of the alimentary functions. Amongst these we would especially specify sarsaparilla, quinine, and minute doses of the muriated tincture, or other mild preparations of iron. Rest and ease from pain must be procured by suitable narcotics, and even when the fatal hectic arrives, we have yet our duty to perform. It is that which is emphatically enjoined in the humane and affecting language of the illustrious Gregory, applicable to every part of our melancholy task in this disease: "*Et profecto in omnibus morbis quum jam ad extrema ventum est, et instantis mortis indicia spem nullam sanationis relinquunt, aliquid adhuc solerti medico faciendum superest: erit enim quoddam in tali*

GALL-STONE.—See JAUNDICE.

GALVANISM. In 1797, Lewis Galvani, professor of anatomy in the university of Bologna, laid, by an accidental observation, the foundation of by much the most interesting and important branch of electrical science. Having suspended some frogs, which he had procured for physiological purposes, by copper hooks to the palisades of his garden, he remarked with surprise, that whenever by the impetus of the wind they were brought in contact with the iron bars of which the palisades were composed, their muscular systems were strongly convulsed. The fame of this extraordinary experiment rapidly spread throughout the entire of Europe. It was repeated and varied in an infinite number of ways, in the cabinet of the philosopher and the theatre of the mountebank, and never failed to excite the curiosity of the learned and the astonishment of the vulgar.* Galvani was fortunate in the time of announcing his discovery. It was an era of mighty changes and of great reforms. In the very capital of continental science, the human mind, just freed from the fetters which long had bound it, became the slave of prejudices by no means unnatural. What was old was rejected, frequently because of its antiquity alone; while every novelty came recommended by irresistible attractions. There was also another and a very different cause to which may, at least in part, be attributed the interest excited by the observation of the Italian philosopher. To many it appeared that a clew was now at length afforded for ascending to the long-sought-for source from which spring the mysterious phenomena of life and organization; and that, in particular, by prosecuting the rout thus pointed out, the nature and cause of nervous energy could not fail of being unfolded.

Galvani was not slow in framing an hypothesis to account for the phenomenon which he had been the first to observe. According to him, a peculiar fluid existed in the nerves of the animal in a state of accumulation, which, rushing through the interposed metals, was precipitated upon the muscles, and produced their spasmodic action. Upon this theory the animal body is but a sort of charged Leyden jar; the nerves representing its internal, and the muscles its external coating; the discharge also being effected in the ordinary manner,

* This experiment is best performed by removing the upper part of the trunk of the animal, drawing off the skin from the inferior portion of the trunk and lower extremities, and cutting away the bones of the pelvis and contiguous soft parts; so that the lumbar vertebræ may remain connected to the thighs by the crural nerves alone. A copper hook is now to be attached to the vertebræ, or made to embrace the nerves, and then hung on a rectangle composed of iron wire, which, by being inclined, is made to come into contact with the pendient limbs.

namely, by establishing a connexion between the oppositely affected surfaces. This analogy was suggested at a very early period, and was for a length of time considered as conferring a high degree of probability on the views from which it originated.

Though this explanation was very generally acceded to, philosophers were by no means agreed respecting the nature of the fluid whose agency it employed. By some it was denominated nervous fluid, under the idea, no doubt, that it was identical with that power on which the functions of the nervous system depend; and this is the opinion which would seem to have been entertained by Galvani himself. His followers, however, usually spoke of the *galvanic* fluid in honour of their master, and to commemorate his discovery.

A different, and, as we shall see, a more correct opinion soon began to prevail. It was very early observed that the same substances which are conductors or non-conductors of the electric, are also conductors and non-conductors of the galvanic fluid. Hence it was by many inferred that the two were identical; a conclusion, however, firmly resisted by the adherents of Galvani, who still continued to view in his experiment the operation of a vital force.

It was at this period that Volta, professor of physics in the university of Pavia, after a diligent study of the phenomenon which at the time engrossed so much of the attention of the scientific world, was led to the discovery of a condition essential to its occurrence, which had escaped all of his predecessors. If the nerves and muscles be connected by a single metal, there are no convulsions; but if by an arc composed of two dissimilar metals, convulsive motions always ensue. Having established this important point, it still remained for him to account for the agency of the two metals, or to explain the precise manner in which they determined the production of the spasms. This he accomplished in the most satisfactory manner, by shewing experimentally that dissimilar metals upon contact assume opposite electrical states; or that the one becomes vitreously, the other resinously charged. Having effected this, the true theory of Galvani's experiment was sufficiently obvious. By the contact of the copper hook with the iron palisades, the latter became vitreously, and the former resinously electric. But when the limbs of the frog touched the iron bars, the free fluids rushed together by the rout thus opened to them, and combining in the body of the animal, produced the spasmodic contractions of its muscular system. Such was the explanation given by Volta.

These views, which appeared but a legitimate deduction from facts, though generally received elsewhere, were not admitted by Galvani. He denied the necessity of a second metal, and quoted indisputable cases of convulsions excited by a single arc, as a refutation of the entire theory.

That contractions are occasionally produced by a single metal, Volta did not deny. More

extended researches, however, upon the electricity developed by contact, enabled him to reconcile such cases with his own views. He found, in fact, that the metals were not the only forms of matter which, when made to touch, acquired the opposite electricities; but that this property belonged to any two heterogeneous substances. Thus, if a disc of wood be made to touch one of marble, an electric decomposition ensues; and the only difference between this case and that of two dissimilar metals is, that the electricities developed possess a much lower intensity. Now, adopting these conclusions, it is easy to solve the objection of Galvani. The metal employed by him may have possibly included a minute quantity of some other metal in the form of alloy; or such may have adhered mechanically to it. Or, should neither of these suppositions be correct, it must at all events, when interposed between the nerves and muscles, have touched, at each extremity, substances of a very different nature from its own; a circumstance which, according to the researches of Volta, was quite sufficient to account for the development of electricity. The facts, therefore, relied upon by Galvani were not only not inconsistent with, but directly deducible from the principles of Volta. It may also be observed, that by means of a single metal we but rarely succeed in producing contractions; and that, when they occur, they are extremely feeble.

When two dissimilar metals are made to touch, the one becomes positive, and the other negative. This was the capital discovery of Volta. The power which produces, in such cases, the electric decompositions, he denominated *electromotive force*, and the substances employed, *electromotors*. All metals, however, it should be recollected, are not equally good electromotors. Thus zinc forms a more efficacious combination with silver than with copper; and a still more powerful one with platina than with silver. As a general rule it may be laid down, that the more two metals differ as to their affinities for oxygen, the more energetically will they act as motors of electricity; to which may be added, that the more oxidable metal invariably acquires the vitreous or positive, and the less oxidable metal the resinous or negative fluid. Such are the uniform results of experiment.

The tension of the fluids liberated by the contact of a single pair of metals, when examined by the most delicate condenser, proves to be extremely feeble; and it even requires considerable address to demonstrate, with this instrument, the development of any electricity at all; though, by means of the frog, the most sensible of all electrosopes, it may, as we have seen, be strikingly displayed. In reflecting, however, upon his fundamental discovery of the development of electricity by heterogeneous contact, it occurred to Volta that by properly connecting several *couples*, their separate powers might be so combined as to evolve the elementary electric fluids in a high state of tension; and, upon submitting this conception to the test of experiment, he had the satis-

faction of finding it fully verified. The following was his method of proceeding. A disc of silver being placed upon a table, one of zinc was laid upon it; and upon this a bit of thin pasteboard soaked with a solution of common salt. Another silver disc was put upon the pasteboard; upon it a disc of zinc, and upon this again a second bit of pasteboard, and so on; similar discs of silver, zinc, and pasteboard being constantly piled upon the preceding, and in the order which has been described. Having superimposed in this manner thirty or forty couples with their intervening pasteboards, upon applying a finger of each hand to the extremities of the column, he received a pretty smart shock, and upon connecting them by copper wires he observed the production of a slight spark. Such was the origin of the celebrated pile of Volta.

The instrument just described is usually known under the name of the *columnar pile*. Several modifications of it have from time to time been invented. But it will be sufficient, with a view to the present article, to confine ourselves to a description of the *voltaic trough*, this being the form of galvanic machine most generally employed, particularly for medical and physiological purposes. It originated with Mr. Cruikshank, and may be constructed as follows. A number of equal plates of zinc and copper, of a square or rectangular shape, are procured; and each plate of zinc being soldered by one of its faces to a plate of copper, the compound plates are then cemented into a rectangular cistern of wood, at distances from each other of about half an inch, care being taken that the contiguous couples shall always present to each other dissimilar faces—zinc, for example, to copper. The cistern, whose breadth is the same with that of each couple, is thus divided into cells; and when the machine is to be rendered active, these are to be filled to within a short distance of the top with an acid solution. On the contrary, when the trough is not in use, it is to be emptied of its acid, and well washed with water to prevent any unnecessary corrosion of the metals. This machine does evidently not differ, in any essential particular, from the original invention of Volta. They are both composed of dissimilar metallic electromotors, similarly arranged in reference to each other, the only differences being, that in the pile they have a vertical, in the trough a horizontal position, and that in the former the couples are separated by a disc of cloth or pasteboard moistened with an acid, while in the latter they are separated by strata of the acid solution itself.

We may now proceed to an examination of the phenomena exhibited by the voltaic apparatus, and of the singular powers which it is capable of exerting. These may be conveniently studied under the four following circumstances:—1. when the circuit is incomplete, that is, when the opposite extremities of the pile are not connected by a conductor of electricity: 2. when the interposed medium is an imperfect conductor, such as water, the acid, alkaline, and saline solutions: 3. when

it is a good conductor, as charcoal or the metals: 4. when the circuit is completed through a living animal. Upon the three first heads, which comprehend the science of galvanism, as it is related to chemistry and general physics, our observations shall be very brief; but upon the fourth we shall dwell with more minuteness, as it includes topics the discussion of which must prove interesting to the physician and the physiologist.

If the upper end of a columnar pile, whose lower end is in connection with the ground, be examined by appropriate means, it will be found to be electrically excited. The pile being supposed to consist of zinc and copper discs, when the former is uppermost the electricity is positive, and negative when the latter crowns the column. The tension also of the electricity is directly proportional to the number of couples; so that in three piles consisting of twenty, forty, and sixty couples respectively, the tensions are as the numbers one, two, three. The lower extremity of the pile, or that which communicates with the ground, manifests, of course, no symptoms of excitement. If the pile be insulated, by building it upon a plate of glass or resin, or suspending it in a dry atmosphere by a silken cord, both extremities will be found charged; the zinc end with positive, and the copper end with negative electricity, while its central point maintains the neutral state. In receding from the centre also on either side, the electric tension, which is at first feeble, goes on augmenting until it attains its maximum at both ends, which are from thence denominated the poles of the pile, from their analogy to the extremities of a bar magnet. It is almost unnecessary to observe that these statements are equally true of the trough, or any other form of voltaic machine. Upon the principles of Volta, also, which we have all along adopted, it would be easy to assign the theory of the accumulation of the elementary electricities at the opposite poles. But from this discussion we purposely abstain, as being one which is destitute of any immediate practical bearing.

Before observing upon the effects produced by the voltaic machine when its poles are connected by conductors, it will be proper to form clear notions upon what is usually denominated the *direction* of the electric current. Upon the theory of Dufay, (see *ELECTRICITY*;) it is obvious that the two kinds of electricity are set in motion at the same instant, and that a current of positive electricity in one direction bespeaks a current of negative electricity in the opposite direction. It is sufficient, however, to confine our attention to one of the elementary fluids, the direction of one determining the course of both; and that pitched upon by common consent is the positive. Whenever, therefore, mention is made of the direction of the electric current, it must be understood that we speak of the positive or vitreous electricity. Thus in the pile itself the electric fluid is said to move from the copper to the zinc end; while through the conducting medium supposed to connect the poles, its rout is alleged to be from

the zinc to the copper. This statement is strictly true of the positive or vitreous fluid, and we limit ourselves to the description of its course alone for the sake of brevity.

In all machines consisting of more than one pair of electromotors the direction of the current is obviously what has been just described; that is, it sets, in the pile itself, from the copper to the zinc end, and, in the arc which completes the circuit, from the zinc to the copper. But in an elementary pile, or one including but a single pair of metals separated by an acid or saline solution, the direction of the current through a wire supposed to connect the plates is from the copper to the zinc, or apparently in an opposite direction to that just described. This, however, is really not the case, as will be obvious upon reflecting that the connecting wire is a part of the copper element of the combination, while the fluid is merely the conductor interposed between the poles. Though, in fact, in this simplest form of voltaic combination the current moves from the copper to the zinc through the wire, and from the zinc to the copper through the fluid, its direction is the same as in a pile of several couples; for the wire is a part of the pile itself, and the fluid the medium which completes the circuit.

When the circuit is completed through imperfect conductors of a compound nature, they undergo decomposition, some of the elements appearing at the positive, others at the negative pole. This fact was first noticed by Carlisle and Nicholson in the case of water, and the researches of other chemists, particularly those of Berzelius and Davy, have shewn that it holds in every variety of compound substance when subjected to the action of a battery of sufficient power.

When the wires usually attached to the poles of a battery for completing the circuit are armed with cones of charcoal, and then approached to each other, heat and light of the most intense description are immediately developed, and the phenomena are equally brilliant in vacuo as in atmospherical air. If the circuit be completed through a fine wire, it immediately undergoes vivid ignition, and finally melts, even though it be composed of platina. And if for wire the different metallic foils be substituted, they burn with scintillations of the most brilliant description.

In more modern times other very singular phenomena have been observed upon passing a galvanic current through a wire, or other conductor, placed in the vicinity of a magnetic needle. When the wire is parallel to and immediately over the needle, a current, whose direction is from south to north, causes a deviation to the left hand, or the west. If the wire, its parallelism to the needle being always preserved, be placed just under it, a deviation eastward, or to the right hand, is produced. If the dipping-needle be now substituted for the compass, and the conducting wire be placed to its west, a depression of the north pole immediately ensues; if to the east, the same extremity is elevated.

These constitute the great discoveries of Ersted, which have given rise to the science of electro-magnetism, and promise, at no distant period, to rectify and generalise, to an extent which could not be previously anticipated, our notions respecting some of the most important of the powers of nature. This brief notice of them is introduced here chiefly for the purpose of rendering intelligible the nature of the galvanometer, an instrument which we shall have occasion hereafter to refer to, and of which it is a sufficient description to say, that it indicates the force of electrical currents by the deviations which they produce in a horizontal magnetic needle, around and in the vicinity of which they are made to circulate through a wire situate in a vertical plane passing through its two poles.

Having glanced thus rapidly at the origin of the science of galvanism, the discoveries of Volta, and the application of his machine as an agent of analysis, and for the production of calorific and electro-magnetic effects, we may now proceed to the more immediate object of this article, namely, the examination of the influence of the pile upon the living system, and the exposition of its therapeutic agencies. The two latter subjects are obviously intimately connected, and should, therefore, be studied in conjunction.

The galvanic current, when brought to act upon the living body, is capable of producing three orders of effects. 1. It produces peculiar sensations. 2. It determines muscular contractions. 3. It is supposed to influence the organs of secretion. Upon these we shall observe in succession.

If a slip of zinc, applied to the tip of the tongue, and a dollar, placed between the gum and upper lip, be brought into contact, a decidedly acid taste is experienced; but if the position of the metals be reversed, the taste will be a decidedly alkaline one. In order to the production of these sensations the tongue must be covered with some moisture, for, when perfectly dry, no such impressions are perceived. Hence it is probable that such sensations are owing, not to any direct action of galvanism upon the tongue, but to the decomposition of the salts of the saliva, and to the consequent development of an acid and an alkali at the opposite poles. Berzelius first noticed similar effects from streams of common electricity directed by a painted wire upon the tongue, or that the vitreous fluid produced an acid, and the resinous fluid an alkaline taste.

When the experiment, just described, with the slips of zinc and silver is performed in the dark, a flash of light is perceived, which is observable not only upon bringing the metals into contact, but also upon separating them from each other; and it is worthy of remark that the flash is most vivid when the zinc or positive metal is in contact with the tongue. A more decided effect may be produced by attaching to the eye-ball, beneath the eye-lid, a slip of tin foil, placing a silver spoon in the mouth, and connecting it and the foil by any

metallic ore. The experiment succeeds also in the light, and whether the eye be open or shut; and at the instant of the contact of the metals the pupil is observed to diminish in size, just as when the eye from comparative darkness is suddenly exposed to the glare of sunshine. The luminous couruscations observable in these experiments are probably the result of the mechanical action of the galvanic fluid upon the retina, for phenomena of precisely the same description may, as is well known, be produced by inflicting a slight blow upon the eye-ball.

Upon the pain produced by galvanism it is unnecessary to dwell. It is an invariable accompaniment of the sudden transmission through, or withdrawal from the body, of a strong electric current. During the completion of the circuit also, a disagreeable sensation is experienced, which becomes extremely distressing if the part of the body at which the current enters, or from which it issues, be deprived of its cuticle, or if there be a sore or cut in the line of its passage. Even pain may be produced by a very feeble current, as is well illustrated by an experiment easily repeated, in which a leech is securely imprisoned by merely placing it upon a crown-piece resting upon a sheet of zinc. From experiments on frogs, M. Morianini infers that the influence of the galvanic fluid on the animal economy is different according as it moves in the course of the ramification of the nerves, or in the opposite direction. In the former case, according to him, it determines convulsive motions alone; in the latter, sensations. These conclusions, however, have been overturned by the recent researches of Nobili, of which we shall presently have to make more particular mention.

When any part of an animal, either still living or but recently dead, is made a part of the galvanic circuit, a shock is experienced, closely resembling that caused by the discharge of a Leyden phial, and the intervening muscles are thrown into momentary convulsive action. Thus if, while the negative pole is touched by the fingers of one hand, the other be brought into contact with the positive end of a voltaic machine, a concussion will be felt in both hands, which will extend to the wrists, the elbow, or even the chest, according to the intensity of the developed electricities. Nor are the pile or any of its modifications essential to the production of such phenomena. In the frog they may be produced, as in the experiment of Galvani, by a single pair of electromotors; and the same is true of the earth-worm, the leech, the niais, and many other cold-blooded animals. The frog, however, is, of all known organized beings, that which is most easily excited by the galvanic stimulus; and hence, and because, generally speaking, it may be procured without difficulty, it has been usually made the subject of such experiments.

The first point of importance to be noticed in reference to the influence of galvanism on

the muscular system is, that a shock is felt, and convulsions are produced, not only when the circuit is completed, but also at the instant when it is broken, and that during the maintenance of the circuit no such effect is perceived. Thus, if a slip of zinc be laid upon the crural nerves of a frog, prepared as described in the note at the commencement of this article, and a copper wire upon either of the lower limbs, when brought into contact, the extremities are convulsed; during the contact there is no contraction, but upon separating the metals from each other, or one or both from the animal, so as to interrupt the circuit, the spasm is renewed. In order, however, to the experimental verification of these phenomena, it is necessary that the circuit be completed or interrupted with rapidity; for if the electric current be gradually admitted into or withdrawn from the body of an animal, no spasms will ensue. This fact is interesting, and is well illustrated by the following ingenious experiment made by Mr. Morianini.* Let a prepared frog be placed between the terminal cups of a *couronne de tasses* composed of a few couples, and which is interrupted at some one point, a single pair of the electromotors being wanting. Upon supplying the place of this couple by two fingers of the same hand, both being perfectly dry, no effect will be produced upon the frog. But if the fingers be kept for a few instants in the cups, upon withdrawing them contractions will take place. When first immersed, the cuticle being quite dry, and in such state a non-conductor, the circuit is in fact not immediately completed. This, however, is effected gradually in proportion as the epidermis becomes soaked with moisture, and hence, upon removing the fingers and thus suddenly interrupting the current, the frog is convulsed. The fluid of the cups in which the fingers are immersed should be pure water.

Having determined the chief conditions necessary to the production, by the pile or one of its elementary couples, of involuntary muscular contractions, we have next to consider whether such effects are at all influenced by the direction which the current takes through the body, or by the nature of the particular tissue which it traverses. The latter topic shall be first discussed.

The muscles of the animal body may, it is well known, be divided into three classes,—the voluntary, the involuntary, and those of a mixed character. The muscles, for example, which move the extremities are of the first kind. The heart is an involuntary muscle, and the diaphragm, though chiefly involuntary, as performing, under ordinary circumstances, its movements independently of the will, is also partly voluntary, inasmuch as these movements may for a time be suspended.

Now upon all three the galvanic fluid exercises a similar power, that is, it stimulates them to convulsive action. The involuntary

muscles are undoubtedly much less affected by it than those which are under the controul of the will; and it has even been contended by some that they were entirely exempt from its influence; an opinion, however, amply refuted by the experiments of Fowler, Nysten, Humboldt, and other eminent physiologists. We shall nevertheless confine our remarks to the voluntary muscles. They constitute the most numerous class, and are, as has been just observed, much more sensible than the others to the voltaic stimulus.

If the nervous chord whose ramifications supply a muscle be cut, the muscle is paralysed, or will no longer contract at the suggestion of the will. This is well known to every physiologist. A similar result also would be obtained by exercising pressure upon the part of the brain or spinal chord from which the nerve originates. From these facts, therefore, which establish that the power of the will in determining the contraction of a muscle is exercised through the nerve which is distributed to it, it would seem a probable inference that the spasms caused by galvanic combinations are also dependent upon some influence propagated through the same channel. Now the conclusion to which we are thus led by analogical considerations seems demonstrated by the following experiment.

Let a frog, prepared as has been already described, be placed upon a common plate, with its crural nerves hooked upon a copper wire, and a slip of zinc laid upon one of its limbs. Upon bringing the metals into contact convulsions will ensue; but if the copper wire be disengaged from the nerves, and made to touch the muscles of the pelvis, or upper part of one of the thighs, upon effecting the contact of the metals as before, there will be either no convulsion, or one of a very feeble description.

If spasms were uniformly wanting in the latter part of the experiment, the conclusion would seem irresistible that the stimulus of electricity, in order to be efficacious in determining contractions, should be conveyed to the muscles through the medium of the nerves. Their occasional occurrence, however, cannot be considered as fatal to such an inference; for the current, in penetrating the muscles, will necessarily meet with nervous fibrils, so that the slight contractions, which are occasionally observed, may be attributed to its motion along these. Consistently also with this solution it may be observed that the experiment succeeds best with electromotors of low power, as copper and platina. With zinc and copper the electricity evolved may be conceived to possess such tension as to enable it to dip into the muscles, and thus pursue its rout along the nerves which it there encounters. That the muscular fibre therefore is passive under the direct influence of the electric current, and that the spasmodic contractions which it suffers, in ordinary galvanic experiments, are the result of some modification of state produced by galvanism in the nerves which supply it, has not only analogy in its

* *Annal. de Chimie*, xl.

avour, but is supported by direct experiment. It is also the conclusion to which M. Nobili* has come, after an elaborate analysis of the various facts and reasonings that admit of being brought to bear upon the subject.

When, then, the galvanic influence is suddenly transmitted through a nerve, or suddenly withdrawn from it, the muscles to which this nerve is distributed are convulsed, but are not at all affected by the immediate action of the electric current. Is this effect independent of the direction of the current? or is it influenced by it? Such are the questions which we have now to examine, and, if possible, resolve.

There are many experiments upon record, most of which may easily be repeated, demonstrating that the electric current produces the most striking effects when passed along a nerve in the direction of its ramifications, or from its origin to its distribution. Thus Volta found that a prepared frog was convulsed by the discharge of a Leyden phial when the nerves were directed to the positive surface, but not when they were presented to the negative coating. Dr. Ure, also, has noticed a similar fact, and illustrated it by the following well known experiment. Let a prepared frog be held by its crural nerves in the left hand, while one of its legs is at the same time laid hold of by an assistant. A bit of silver held in the other hand is now made to touch a slip of zinc in the second hand of the assistant; and, upon contact, there will be either no convulsions, or they will be very feeble. Let the experimenter and his assistant now exchange metals, and, upon repeating the contact, very vivid convulsions will take place. Here, in the case where the spasms are decided, the electricity obviously moves from the nerves to the muscles, or in the direction in which they ramify, the zinc being the positive metal.

The preceding is but a modification of the celebrated experiment of Mr. Lehot. To the crural nerves of a prepared frog he attached a slip of zinc, and, holding one of its legs in his left hand, he brought the zinc in contact with a surface of mercury, and found that, upon touching the same surface with his right hand, so as to close the circuit, convulsions ensued. Upon, however, disengaging the zinc from the nerves, and bringing both into contact with the mercury, a leg of the frog being held, as before, in one hand, and the zinc plates in the other, no contractions were observed. The same phenomena also presented themselves upon using a couple composed of any two of the following substances: zinc, lead, tin, mercury, bismuth, copper, silver, and plumbago. The conclusions arrived at by Lehot by means of single couples, were subsequently drawn by Bellingieri, who operated with piles. The experiment succeeds perfectly with a combination of a few couples. But when the pile is powerful, there is a convulsion, in whatever direction the current be made to traverse the nerve. It is, however, always much feebler in the case

of the inverse than of the direct rout, and may probably be accounted for by a few recurrent fibrils conducting some of the electric fluid to the muscles to which they are distributed. On the whole, then, though it would probably be premature to infer, from what precedes, that inverse currents are incapable of producing muscular spasms, it certainly appears sufficiently proved that they are much less adapted than direct ones for the production of such effect.

The most curious fact connected with this interesting subject still remains to be mentioned. To produce the convulsions of a muscle by galvanism, it is not necessary that the electric current should extend to it, or, in other words, that it should be comprehended in the circuit. It is quite sufficient that the latter be completed through ever so small a portion of the nervous trunk which supplies the muscle. By operating in this way both with direct and inverse currents, and noting the phenomena which presented themselves, both upon closing and upon opening the circuit, M. Nobili arrived at the results included in the following table. In order to their being perfectly understood, it should be premised that the experiments were performed at four consecutive periods, separated from each other by equal intervals, and that the excitability of the animal was, as will be readily anticipated, constantly diminishing.

FIRST PERIOD.

<i>Direct current.</i>	<i>Inverse current.</i>
Closing, Contractions.	Closing, Contractions.
Opening, ditto.	Opening, ditto.

SECOND PERIOD.

<i>Direct current.</i>	<i>Inverse current.</i>
Closing, Strong contractions.	Closing, No contractions.
Opening, Feeble do.	Opening, Strong do.

THIRD PERIOD.

<i>Direct current.</i>	<i>Inverse current.</i>
Closing, Strong contractions.	Closing, None.
Opening, None.	Opening, Strong.

FOURTH PERIOD.

<i>Direct current.</i>	<i>Inverse current.</i>
Closing, Contractions.	Closing, None.
Opening, None.	Opening, None.

Such were the results almost uniformly obtained by Nobili. Exceptions, however, occasionally occurred, but these were almost always observed in the case of frogs in a feeble or exhausted state from want of food, or long confinement. It is fit also to state that his experiments were made in autumn, at a temperature varying between 50° and 59° Fahrenheit, and with a single pair of feeble electromotors, as copper and platina. With piles, or even a more powerful couple, as zinc and silver, the above order of effects is not exactly observed. The difference, however, is not material, it consisting merely in this, that the last contraction which disappears is that consequent, not upon establishing the direct, but upon interrupting the inverse current.

* Annal. de Chimie, xlv. page 60.

The order of effects represented in the table, and what he denominates the law of the contractions, Nobili found to continue the same whether the circuit be completed through an insulated portion of nerve, or, as in ordinary experiments, through the nerves and muscles; a circumstance from which he does not fail to deduce another argument in favour of the conclusion which we have already drawn, namely, that the muscles are stimulated to contraction by the electric current only when it operates through the medium of the nerves. The argument is undoubtedly a strong one, and, when combined with those already advanced, may, we think, be considered as deciding the question.

From the entire of the preceding facts the following conclusions may be deduced.

1. The muscular fibre is insensible to the stimulus of galvanism when applied directly to it.

2. When an electric current is suddenly transmitted through a nerve to a muscle, or in the inverse direction, the muscle is thrown into spasmodic action.

3. The same effect is produced upon suddenly interrupting the electric current when moving in either of the directions just described.

4. Precisely similar results to those mentioned in the two preceding paragraphs are obtained upon completing the circuit through a portion of the nervous trunk which is distributed to a muscle, and upon interrupting it after being so completed.

5. The most powerful contractions are produced by transmitting the direct current.

6. The next, in point of energy, are those which occur upon interrupting the inverse current.

As an apt conclusion to the preceding topics we shall briefly notice here a theory of the cause of muscular contractions not long since put forward by Prevost and Dumas.* It is founded upon two recent discoveries, the one in anatomy, the other in electro-magnetism.

By microscopical observations upon the abdominal muscles of a frog, these physiologists ascertained that, during contraction, the muscular fibres underwent no absolute shortening, but that each was thrown into a zigzag shape, in virtue of which its extremities were made to approach each other. They also found that the flexions invariably occurred at the same points of each fibre, and that a nervous twig passed through the vertex of every angle produced by the contraction, and in a direction perpendicular to the fibres. Such are the anatomical facts essential to their hypothesis.

For the electro-magnetic discovery which they make use of in their theory we are indebted to Ampère, who found that two parallel galvanic currents, moving in the same direction, attract, and in opposite directions, repel each other.

To account, upon the basis of the preceding facts, with Prevost and Dumas, for the contraction of a muscle, it is only necessary to suppose that galvanic currents are made to pass in the same direction through the nervous fibrils which supply it. These, being parallel, must be the subjects of a mutual attraction, which will bring them closer to each other, and thus determine that sinuous arrangement of the muscular fibres they intersect, which is demonstrable by means of the microscope.

If this theory were a representation of facts, it has been suggested that we should be able to demonstrate the existence of the electric currents which it assumes. Accordingly, numerous experiments have been made with this object, but the results have been very discordant. Upon connecting, for example, two needles passed through a nerve, at a short distance from each other, with the cups of a galvanometer, M. Person* could observe no deflexion of the magnetic needle. Mr. Paulliet† found a deviation when the needles were of iron, but none when they were composed of gold or platina, and therefore attributed the electricity which was set free in his experiments to chemical action. Lastly, Mr. David,‡ operating upon the sciatic nerve of a rabbit carefully insulated from surrounding parts, found the needle quite stationary as long as the animal was at rest, but observed a decided deviation whenever the muscles it supplied were thrown into action. The subject is one of considerable difficulty, and can be prosecuted with a prospect of success by him only who combines, with manual dexterity, a competent knowledge of anatomy, chemistry, and general physics. In the present stage of the inquiry there are no sufficient data for enabling us to decide one way or the other. We do not, however, hesitate to avow our conviction, that the balance of evidence is in favour of the hypothesis which views the nerves as the media for the circulation of electrical currents through the animal body. It should be recollected that, when such are not indicated by the galvanometer, it would be unsafe to conclude, on this account alone, that they do not exist; for, in the first place, this instrument is not adapted for the detection of any but continuous currents, and, in the second, in order that we may be able to exhibit even these, according to the method of experimenting usually adopted, it is indispensable that the nerves be less perfect conductors of animal electricity than the wire of the galvanometer,—a condition which, possibly, is, in point of fact, not fulfilled.

But it will be asked, what is the origin of the electricity they convey? Whence do the galvanic currents proceed? Upon this head, it must be confessed, nothing having a demonstrative character can be adduced. It is true

* Journal de Physiologie, tom. x.

† Ibid. tom. v.

‡ Journal of the Royal Institution, No. iv. page 183.

* See Edwards, Sur les effets des agens physiques sur la Vie. Appendice.

we may suppose the brain, with its production into the vertebral column, to constitute a sort of ever-acting electric organ, from which currents are transmitted along certain of the nerves at the suggestions of the will, and may conceive with Mr. Herschel,* that parts of it are spontaneously discharged at "regular intervals, when the tension of the electricity developed reaches a certain point," and that thus "the pulsations of the heart" and the contractions of the other involuntary muscles are produced. Such views are plausible, nay, even probable, but they do not admit of experimental proof, and must be considered as deriving their principal support from their apparent sufficiency to explain phenomena. Some, indeed, observing in the brain and spinal chord nothing analogous in point of structure to our artificial electromotors, and viewing the animal system as composed of an aggregation of tissues, all of which are conductors of electricity, find a difficulty in admitting that the elementary electric fluids can be either separated or accumulated within it. Such objectors, however, should recollect, first, that for the decomposition of the electric fluid the sole contact of dissimilar substances is sufficient, a condition amply fulfilled in the animal body; secondly, that there is both a decomposition and an accumulation effected by the pile, though composed exclusively of conductors; and, thirdly, that certain animals, such as the torpedo, gymnotus, and silurus, are undoubtedly possessed of the powers in question.

There is indeed another class of objectors to whom it is proper briefly to advert. The views here suggested, it will be alleged, tend to conclusions hostile to religion, inasmuch as they profess to explain the animal functions upon principles purely material. This is an objection which, when honestly urged, usually proceeds from weak and timid men. Our reply shall simply be, that while we recognize throughout the entire of the organized world the operation of a variety of secondary causes of a mechanical kind, we are, by the very contemplation of them, compelled to admit the existence of other agents higher in the chain of causality, and in their nature totally different from and independent of matter.

In the thirty-third volume of the *Philosophical Magazine*, page 488, there is a paper from the pen of Dr. Wollaston, containing the earliest conjectures to be met with in reference to the influence of galvanism upon the secreting organs. Reflecting upon the wonderful powers of decomposition and transfer which Davy had lately shewn that the pile was capable of exerting, and upon the fact of a distinct electric apparatus having been detected in certain fishes, it occurred to this eminent philosopher that the products of secretion might be due to electricity of low intensity; and he even suggested the nature of the secretions, as to acidity or alkalinity, as a test of the species of electric fluid accumulated in each organ. Thus

the milk, the sweat, and the urine, as being all acid, should, upon this principle, be considered as proceeding from organs in an electro-positive state; while the bile and different serous secretions, as containing a free alkali, would argue an electro-negative state of the parts from which they are discharged. In support also of his hypothesis he quotes the result of an experiment in which very feeble electricity, such as is developed by a single couple composed of zinc and silver, effected the decomposition of common salt dissolved in two hundred and forty times its weight of water, and the transfer of its alkaline base through a slip of bladder tied over the end of the glass tube in which the solution was contained. Mr. Maturci has recently* revived the experiment and the views of Wollaston, and added the important observation that the animal principles occurring in the several secreted fluids abound in elements of corresponding electrical relations, or that in the acid, oxygen and azote, in the alkaline, carbon and hydrogen, are chiefly to be found. Dr. Wilson Philip, however, is unquestionably the individual who has espoused this theory with most zeal, and illustrated it with most success. His researches are extremely interesting in themselves, and have fixed, in an especial manner, the attention of physiologists. We shall, therefore, briefly notice them in this article, and shall commence with a description of his principal experiment.

The par vagum, or eighth pair of nerves, which are chiefly distributed to the stomach and lungs, were divided in the necks of several rabbits, shortly after having fed upon parsley. Their respiration was thus immediately rendered laborious, nausea and fruitless attempts to vomit supervened, and the animals finally died, apparently of suffocation. Upon opening their stomachs, also, the parsley was found quite unaltered, from which he concluded that the secretion of the gastric juice had been suspended. The same experiment was then performed upon other rabbits, with this difference, that galvanic currents were sent to the stomach, by applying one of the poles of a small pile to a slip of tin foil rolled round the lower ends of the divided nerves, and the other to a disc of silver laid upon the epigastrium. In all these cases dyspnoea and tendency to vomit were wanting, and the animals being killed, after the currents had been continued for twenty-six hours, the parsley was found perfectly digested, and the stomach of each exhaled the odour peculiar to this organ during digestion. From experiments such as these, very frequently repeated, and always with the same results, Dr. Philip concludes that the secretion of the gastric juice is under the control of the nervous influence, and that this latter is identical with, because it may be replaced by, the power developed by galvanic combinations. Dr. Philip, however, does not confine himself to this inference, which, if not rigorously established, would at least appear supported by plausible

* Lardner's *Cyclop. Discourse on the Study of Natural Philosophy*, p. 343.

* *Annales de Chimie et de Physique*, March 1830, p. 256.

arguments; but goes the extent of asserting that "galvanism is capable of performing all the functions of the nervous influence in the animal economy;" or, to abide by his own enumeration of these, that, besides "combining the elementary parts of the blood in the formation of the secreted fluids, it conveys impressions to and from the sensorium, excites the muscular system, and produces an evolution of caloric from arterial blood." His researches, it must be admitted, have not been sufficiently extended to justify so sweeping a conclusion; for, beside the experiments just detailed, and which relate to digestion alone, but one having a different scope would appear to have been performed by him. Upon passing the galvanic current through blood recently drawn from the carotid arteries of a rabbit, he states that he observed a rise of temperature of 3° Fahrenheit, or from 98° to 101°. This experiment, however, is far from being conclusive, and must, at all events, be considered as furnishing much too narrow a basis for the theory which he builds upon it, namely, that animal heat is due to currents of electricity which are ever circulating through the contents of the arterial branches of the sanguiferous system.

Nor have the conclusions of Dr. Philip, in reference to the gastric secretion, nor the alleged facts upon which he professes to found them, met with universal adoption. In 1823,* M.M. Breschet and H. M. Edwards undertook the investigation of this contested subject, and by a number of experiments, apparently conducted with all the precautions necessary to insure accuracy of result, conceived that they had established the following propositions:—

1. The simple section of the pneumo-gastric nerves retards, but does not entirely prevent, the digestive process.
2. The excision of a portion of them almost completely suspends this function.
3. In both the preceding cases digestion is restored by the transmission of electric currents along the nerves to the stomach.

But from subsequent researches, made in conjunction with M. Vasseur,† these physiologists were led to believe that galvanism acted merely as a stimulant upon the glands which secrete the gastric fluid, and that similar effects might be produced by any thing causing a mechanical irritation of the lower ends of the divided nerves. There is also another important point on which they differ from Dr. W. Philip. The latter asserts that the section of the par vagum suspends digestion by preventing the secretion of the gastric juice, the muscular power of the stomach continuing unimpaired; while Breschet, Edwards, and Vasseur contend that the stomach is paralyzed by the division of these nerves, and that the interruption of the digestive process is to be ascribed to the cessation of those motions in virtue of which the several parts of the alimentary bolus are brought into successive contact with the secreting surface of this organ. Were these

conclusions clearly established, the theory which represents secretion as a galvanic function could scarcely be maintained. In justice, however, to Dr. Philip, it should be mentioned that Mr. Cutler,* operating under the direction and with the assistance of Dr. Philip himself and of Mr. Brodie, was not enabled, by any means of mechanical irritation, to produce those effects which are, upon all hands, admitted to follow upon the due application of electric currents. The chief of the above objections is thus invalidated, if not overturned; so that we do not hesitate to assert, contrary to an opinion very generally expressed, that the question is still open for discussion, and has by no means been set at rest by the researches of the French physiologists.

Application of galvanism to the treatment of diseases.—Having disposed of the supposed agencies of galvanism in carrying on the functions of the healthy body, we are in a better predicament for appreciating its influence as a medicinal agent. This is the only topic, legitimately within the scope of the present article, which remains to be discussed.

The first therapeutic application of the pile, of which we shall make mention, was suggested by Prevost and Dumas.† Reflecting upon its powers of decomposition, particularly as illustrated by the celebrated discoveries of Davy, it occurred to these physiologists that it might be successfully employed for breaking down the materials which compose urinary calculi, and that thus the necessity for one of the most formidable of surgical operations would be obviated. Their idea, in fact, was to introduce into the bladder a canula containing two platina wires, carefully insulated from each other, and whose internal ends should be brought in contact with the stone, while their external extremities were put in connexion with the poles of a powerful battery. Upon the established principles of electro-chemistry they expected that it would be resolved into its acids and bases, the former assembling at the positive, the latter at the negative pole, and that, in this way, its gradual disintegration would be effected. A preliminary experiment, made upon a fusible calculus placed in a basin of water, and a second, upon a stone of the same kind, introduced into the bladder of a dog previously injected with tepid water, gave encouraging results. The former, submitted for eight hours to the action of a battery composed of one hundred and twenty couples, and charged with muriatic acid diluted with thirty times its weight of water, was reduced from ninety-two to eighty grains, and, in eight additional hours, was so disintegrated as to break into small crystalline fragments, upon the application of the slightest pressure. The latter underwent similar changes, and they found that no irritating effect whatever was produced upon the bladder, however powerful the pile which they employed. This proposal, however, has, we believe, never been acted on. It is obvi-

* Med. Chir. Review, vol. iii. p. 589.

† Journal de Physiologie, tom. iii. p. 217.

ously not applicable at all to the lithic calculi, which constitute by much the most numerous variety. The manipulations, also, are so difficult of execution, the process is necessarily so slow, and the result so uncertain, as to leave us at no loss for conjecturing why the preference should hitherto have been invariably given to lithotomy. Nor, considering the recent admirable invention of grinding down the stone, is it likely that the value of the galvanic method will be tested upon any future occasion.

The next application of galvanism to be noticed is in the treatment of asphyxia, whether proceeding from strangulation, drowning, narcotic poisons, the inhalation of noxious gases, or simple concussion of the cerebral system. In all these cases the interrupted current, that is, a succession of shocks, should be resorted to, the battery should be pretty powerful, and care should be taken that the electricity be as much as possible confined to the nerves, and that it be sent along them in the direction of their ramifications. The experiments of Nobili and Ure, already detailed, sufficiently demonstrate the propriety of attending to these particulars. The chief object in asphyxia being to restore the circulation of the blood and the respiratory movements, the galvanic influence should be principally directed to the organs upon whose actions these depend; and towards accomplishing this, no plan appears more likely to be efficacious than that which has been recommended by Dr. Ure, and which consists in laying bare the sheath which encloses the par vagum and great sympathetic nerve, touching it with the wire connected with the positive pole of a battery, and, while one extremity of the negative wire is pressed under the cartilage of the seventh rib, drawing the other along the upper edges of the plates of the last trough, towards its copper end. In this way, a rapid succession of discharges, each succeeding one of which exceeds the preceding in intensity, is sent to the lungs, the heart, and the diaphragm, that is, to the organs whose functions we are most anxious to revive. Before attempting the operation of laying bare the nerves, the effect of merely pressing the positive wire upon the region of the neck corresponding to their position should be tried. Operating according to the former method, and with a battery composed of two hundred and seventy four-inch plates, upon the body of a criminal executed in Glasgow, Dr. Ure renewed the action of the diaphragm, and produced other effects of such an impressive description as to have induced him to hazard the opinion that, were it not for the injury which the subject of his experiment had sustained from the preparatory dissections, he would, in all probability, have been restored to life. This opinion, however, was probably a too sanguine one, for his experiments, repeated in the winter of 1829, with all the necessary precautions, by the professors of the Irish College of Surgeons, gave much less striking results. The voluntary muscles were, it is true, thrown into strong convulsive action, but all attempts to restore the respiratory movements were entirely unsuccessful. The mechanical

injuries, indeed, sustained occasionally by the spinal marrow, and always by the larynx of individuals who perish by hanging, at least when they have fallen from a considerable height, preclude the possibility of complete recovery from any means whatsoever.

In asphyxia produced by concussion of the brain, there are strong reasons for believing that galvanism, properly applied, would prove extremely useful. This conclusion seems to have been drawn first by Mr. Goudret,* who had his attention particularly called to the subject by witnessing the death of an individual in the Ukraine who had fallen on his head from his horse, notwithstanding the sedulous application of all the analeptic means familiar to the physician. Upon his return to Paris he undertook an experimental examination of the efficacy of the pile in such cases, and found his expectations more than verified. In his first experiment, a rabbit, which had been to all appearance killed by a few violent blows inflicted with the hand upon the back of the head, was perfectly recovered by a succession of shocks, continued for half an hour, from a machine of thirty couples, and transmitted between the eyes, nose, and meatus auditorius externus, on the one hand, and different parts of the spine of the animal, on the other. In a second trial made with a stronger rabbit, the method just described did not produce the desired effect within the space of thirty minutes; but, upon removing the cuticle from the spine by the water of caustic ammonia, and then applying the pile as before, at the end of the second half hour the animal was restored to life, though it continued paralytic for a few days in its hinder extremities. Similar experiments have more than once been performed by the writer of this article, without any knowledge of the previous researches of Mr. Goudret.

In a note appended to the communication of M. Goudret, Majendie states that he, Paviilet, and Roulin had repeatedly succeeded in recovering, by means of the pile, rabbits asphyxiated by submersion in water for more than a quarter of an hour, and adds the important remark that in such experiments patience on the part of the operator is particularly indispensable, inasmuch as, in cases finally successful, reanimation was often not achieved for full thirty minutes. These results illustrate, much more forcibly than the experiments of Ure upon the murderer Clydesdale, the value of galvanism in the treatment of persons recently drowned, and the propriety of his recommendation that a voltaic battery should be included amongst the means of resuscitation provided by the Humane Society.

There can be little doubt that the pile would prove equally useful as a stimulant in cases of poisoning by narcotic drugs, or the inhalation of irrespirable gases, as in those already noticed. Experiments performed upon the lower animals justify this conclusion, though galvanism is not usually mentioned by toxicologists amongst

* Journal de Physiologie, vol. iv. p. 382.

the curative means to be resorted to on such occasions.

Of all the diseases to which the human body is subject, paralysis is that in the treatment of which the galvanic shock is most frequently applied. Its peculiar effects upon the muscular system, already so minutely dwelt upon, and the fact of its possessing the power of throwing even the muscles of a paralytic limb into convulsive action, have both suggested its use, and caused the highest expectations to be formed of its efficacy in the treatment of this affection. Nor have these anticipations proved entirely illusory. Galvanism has often of itself completely removed certain forms of such disease, and it is almost always a useful auxiliary to other lines of treatment. It should, however, be borne in mind that it is not equally applicable in every variety of paralysis. In cases, for example, of hemiplegia following a recent apoplectic attack caused by the extravasation of blood into the substance of the brain, it would obviously be absurd to expect any advantage from such a source. But when there is reason to believe the effused blood has been removed, and that the hemiplegia still continues, the pile may be advantageously resorted to for the purpose of stimulating the nerves, and thus rousing them to the performance of those functions which would appear, in such case, suspended from desuetude alone. It is, in fact, in paralytic affections of a purely functional kind, or which do not depend upon organic disease of the nervous system, or pressure exercised upon any part of it, that the agency of the pile can be rationally resorted to by the medical practitioner. Under this head may be ranged general or local paralysis arising from exposure to cold, palsy of the wrists from the absorption of lead, and many varieties of deafness and amaurosis. In all these cases, as the nerves are to be stimulated to increased action, an interrupted current must be employed, in the application of which the method of Ure should be followed, and all those particulars attended to which have been detailed in connexion with the subject of asphyxia. The discharges of a galvanic battery and a Leyden jar produce sensations so analagous as to render it probable that they affect the living body in the same way, and that they may, therefore, be indifferently applied as stimulants to the nervous system. The pile, however, possesses many advantages which do not belong to the electrical machine. The quantity of electricity which it sets in motion is vastly greater, a peculiarity which may probably confer upon it a higher degree of medicinal power. There is no difficulty in bringing it into action in any kind of weather. The shocks it gives may be more exactly graduated, and admit of being directed with facility to organs which it is difficult, if not impossible, to subject to the influence of the common electric spark. This latter circumstance is most deserving of attention. To submit, for example, in cases of deafness, the auditory nerve to galvanic action, it is sufficient to introduce a wire connected with one of the poles of a battery into the affected ear, and the

other wire into the opposite ear, the circuit being then rapidly broken and completed a number of times by an assistant, according to the method recommended by Dr. Ure, and which has been already so often alluded to. In amaurosis the galvanic shock may, by obvious means, be transmitted at pleasure through the ball of the eye, so as to traverse the retina, or be confined to those twigs of the first branch of the fifth pair of nerves which ramify on the forehead above the orbit, and upon the state of which alone Majendie has shewn* that gutta serena often depends. In aphonia the circuit may be completed through the organs chiefly concerned in the production of the voice, by placing a shilling upon the tongue, and touching it with the negative wire of a battery whose other pole is alternately brought in connexion with, and separated from, different parts of the external larynx, a method successfully employed by Mr. Miles Partington in a case, the particulars of which he details in the *London Medical and Physical Journal*, No. 294. These are instances of affections which have often yielded to the voltaic pile, but upon which the powers of the ordinary electrical machine scarcely admit of being brought to bear.

The shocks of the pile are not only adapted to the various forms of paralysis, but also to the different other diseases for which the sparks of the machine, and the discharges of the Leyden phial are prescribed. These it is not necessary to recount here, as they have been already enumerated in the article on *ELECTRICITY*, to which, therefore, we shall content ourselves with referring.

Whenever galvanism is intended to produce an exciting effect, it must be exhibited so as to produce shocks, or in the form of the interrupted current. There are, however, certain affections in which it is conceived most beneficial when flowing in a continuous stream, the specific effects of it when thus applied being supposed of a sedative kind. This opinion of the difference of action of the voltaic fluid, in the two conditions of it just described, does not rest upon mere conjecture. It is based upon the observation of medical electricians, and is, in particular, sustained by the following experiments. If a prepared frog be subjected to a quick succession of discharges by means of a feeble pile, or even a single couple composed of zinc and silver, its muscles are rendered permanently rigid, and it exhibits all over the condition of a tetanic patient; but upon now passing through it for some time a continuous current in the opposite direction, the muscles gradually relax, and finally attain their natural state. Again, if a recently prepared frog be submitted for some time to an uninterrupted current of galvanism, its excitability seems in a great measure destroyed; for upon subsequently applying shocks, by alternately opening and closing the circuit, either no spasms or very feeble ones will be produced. From facts such as these, Nobili† concludes that all con-

* *Journal de Physiologie*, vol. vi. p. 156.

† *Annales de Chimie*, tom. xlv.

vulsive affections, not excepting tetanus itself, may probably admit of being controuled by galvanism, but that in these the method of its administration should be the opposite to that for paralysis, or, that instead of the interrupted, the continued current should be resorted to, and that to obtain the maximum tranquillizing effect, the electricity should be transmitted along the nerves in a direction contrary to that of their ramifications.

It is probably upon the same principle that the efficacy of the following galvanic treatment of an epileptic patient by Dr. Pearson,* depended. The cuticle having been removed by a blister from the back of the neck and inner side of one knee, these parts were covered with bits of moistened sponge, upon which slips of linen were laid, and over all discs of silver and copper, the former metal being applied to the neck, the latter to the knee. The discs were then connected by a copper wire, which was attached to each by soldering, and enclosed in a pouch composed of chamois leather, so as to be insulated from adjacent parts. This apparatus having been applied for six months, a case of epilepsy which had resisted every other line of treatment was completely cured. It was found to continue in action for ten or twelve hours, after which it became necessary to clean the plates, and renew the pledgets of sponge and linen.

Galvanism in the form of the continued current has also been strongly recommended by Dr. Wilson Philip for the treatment of what he denominates habitual asthma, that is, simple dyspnœa, unaccompanied by pulmonary spasmodic action, or any tendency to thoracic inflammation. This particular application of it was suggested to him by the results of those experiments of his already discussed, in which, after the excision of portions of the par vagum on each side of the neck in rabbits, a stream of voltaic electricity not only restored the digestive process, but also removed the difficulty of breathing. His method was to apply a disc of silver to the nape of the neck, and another to the epigastric region, and then press the positive wire of a galvanic trough against the former, and the negative wire against the latter. His machine consisted of from eight to sixteen pairs of four-inch plates, and was charged with muriatic acid diluted with one hundred and twenty times its weight of water. The circuit was always maintained until decided relief was experienced, which usually occurred within from five to fifteen minutes. In every instance a suspension of the dyspnœa was thus effected, and in many cases the cure was permanent. The success which Dr. Philip experienced in the treatment, upon this plan, of habitual asthma, led him to peculiar views respecting the pathology of this affection. The disease he conceives to consist in some impediment residing in the nerves to the transmission, from the brain, of galvanic influence, and the artificial electric current he supposes to operate by removing such impediment.

When the wires attached to the extremities of a trough are introduced into any animal fluid containing albumen, this latter principle, as was first shewn by-Brande, separates at the positive pole, in the coagulated state. It has hence been suggested that galvanism might be applied to the important purpose of coagulating the blood within an aneurismal tumour, and thus removing the disease without resorting to the ligature. Experiments have been performed on rabbits by M. Velpeau, which demonstrate that the desired effect may frequently be produced by merely inserting a number of needles into the circumference of an artery, so as to present a mechanical impediment to the circulation through it. There can, however, be no doubt that coagulation and its wished-for consequences would, with much more certainty, be determined by completing the circuit of a pile for a few instants through each pair of opposite needles; but we are not aware that this method has as yet attracted the attention of the practical surgeon.

If the connecting wires of a common pile be made to touch a cut or ulcer within a short distance of each other, the animal fluids undergo the coagulation just described, and, by properly shifting the wires, this effect may be extended to the entire surface. With a machine consisting of from forty to fifty couples the effect resembles that which would be produced by a solution of nitrate of silver containing about five grains in the ounce of water; but, with a battery composed of two or three such troughs, the action is much more intense, and there is almost immediately formed an eschar of very considerable thickness. Galvanism may, therefore, be used as an escharotic, and this application of it has actually been made, and is strongly recommended by M. Pravaz,* to the bites inflicted by rabid animals. He details several cases in which this practice was successful, in one of which the cauterization was not resorted to until fifty-four hours after the reception of the bite. The battery which he used was of low power, consisting of only two troughs, containing between them but fifty pairs of electromotors. The eschar was usually detached on the eleventh day, and the cicatrization completed on the seventeenth.

In 1811 Mr. Berlioz† revived in Europe a curative process long practised in the east, particularly in China and Japan, and which is usually known under the name of acupuncture. He was also the first who proposed to combine with it the galvanic influence, a suggestion which has recently been very extensively acted upon, especially by the French physicians. *Electro-puncturation*, as it is usually denominated, is performed by inserting in the ordinary manner two or more needles into the part or organ affected, and then touching these with the wires from the poles of a feeble galvanic machine, the contacts being occasionally suspended and renewed, so as to

* *Revue Médicale*, Decembre, 1830.

† *Edinburgh Med. and Surg. Journal*, vol. xxvii. p. 191.

* *Revue Médicale*, vol. iii., p. 323.

produce a succession of shocks. It has been chiefly employed by Cloquet at the Hospital of St. Louis, and from the reports of his friend Pelletan and his pupil Dantes, and from the treatise of the Chevalier Sarlandier, it would appear to be a most powerful means of combating morbid action. The diseases in which it has been found most advantageous are the different forms of rheumatism and neuralgia; (in the latter affection the needles should be inserted in the course of the principal nerve, and the galvanic current transmitted in the direction of its ramification;) next in spasmodic affections, as muscular spasm, hysteria, and traumatic trismus; convulsive hiccup and vomiting; periodic epilepsies, preceded by pain in the mamma, and, lastly, in inflammatory attacks, such as contusions attended with extravasation and great pain upon motion, ophthalmia, pleurisy, carditis, and even erysipelas. It has also been used, and, according to Mr. König,* with success, for promoting the absorption of the effused fluid in ascites; and Carraro† has proposed it for the treatment of asphyxia. In paralysis it is admitted to be of little use, except for relieving the pain, which is frequently the most distressing accompaniment of such disease. Amaurosis, however, when depending upon neuralgia, is said to be an exception to this statement. A well-marked case, also, of paralysis of the muscles of the right side of the face, accompanied by neuralgia of the portio dura on the same side, is related by M. Montault,‡ which was cured in about a week by inserting a needle through the nerve at its exit from the stylo-mastoid foramen, and four others in the course of its principal branches, and transmitting from the former to the latter a number of shocks once a day, from a pile of thirty couples.

Admitting the efficacy of electro-puncturation in all these complaints, it is very difficult to form any plausible hypothesis as to the manner in which it acts. Some theories have indeed been hazarded on the subject; they are, however, so vague, contradictory, and insufficient, that it would be a complete loss of time to enter upon an examination of them.

In the therapeutic administration of galvanism, the feelings of the patient must be our guide as to the strength of the charge which should be employed in each particular case. Some will sustain with impunity the shocks of a battery which would prove most distressing and injurious to others. The dose may be graduated to any required degree of nicety by properly varying the interval between the conducting wires, for upon this, with a given machine and exciting fluid, will depend the degree of energy of the developed electricities. The strength, in fact, of the galvanic shock, as is well known, depends not upon the size, but the number of the couples which compose the battery. It is, however, influenced by the

degree of concentration of the acid solution, and also by the interval between the adjacent pairs of metals, being connected with the latter in an inverse, and with the former in a direct ratio. The distance between the couples in the common trough should not exceed an inch, and for general purposes the best solution to employ is water containing one-twentieth its weight of strong nitric acid, and one-sixteenth of oil of vitriol. The wires used for completing the circuit should be furnished with insulating handles composed of glass, and be armed at their free extremities with balls of brass, or, what answers better, of silver, gold, or platina. Should such be wanting, silver discs (shillings will answer well) should be laid upon the parts of the body between which the current is to be made to pass, their position being occasionally changed to prevent the skin beneath from being injured: The subjacent cuticle, also, being a non-conductor, should be moistened with a solution of sal ammoniac or common salt.

We shall now conclude by a recapitulation of those general principles of practice laid down in the article on electricity, and which are equally applicable to the present subject.

1. Feeble powers should always be first tried; these should be gradually augmented, and the use of such finally persisted in as, without producing any violent effects, appear to make a decided impression on the disease.

2. Galvanism, as a remedial agent, must not be hastily given up because of its beneficial effects not immediately appearing, for these, generally speaking, require considerable time to be developed.

3. The pile should not be relied upon exclusively in the treatment of diseases, but should rather be considered as auxiliary to other methods of cure.

4. To the preceding we shall add, that, in cases where the continuous current may be deemed most advisable, it would be well to resort to machines composed of plates having an extended surface, there being reason to suspect that the curative influence of galvanism in this form depends not upon its intensity, but upon the quantity of it which is set in motion.

(James Apjohn.)

GASTRALGIA. See GASTRODYNIA.

GASTRITIS, from γαστήρ, the stomach. This term is commonly used to express an inflammation of all the tunics of the stomach, with the exception of its serous covering; but as it is now generally believed that this diseased action commences in the mucous membrane and glands, the term is employed to designate an inflammation of the internal tunic, which may or may not affect the remaining tissues, from the violence or chronicity of the disease, the habit of the patient, &c.

The stomach is admitted to be one of the most important of organs: its existence forms a distinguishing characteristic of most classes of animals; its function is the foundation of

* Revue Médicale, April, 1830, p. 120.

† Edinburgh Med. and Surg. Journal, *supra* citat.

‡ Revue Médicale, January, 1830, p. 63.

all animal organization; it is placed, as it were, in the centre of the economy; it is abundantly supplied with nerves of animal and organic life; and its sympathies are more remarkable, direct, and numerous than those of any other organ. These considerations explain the severity of many cases of gastritis; its great variety of symptoms; the fatal nature of the disease in its more acute forms, and its danger in all cases.

In a former article the history and pathology of enteritis were described; in this we shall consider solely the localization of inflammatory disease in the stomach.

In the article ENTERITIS the difficulty of investigating the symptoms of inflammation of the stomach, as distinguished from those of enteritis, was alluded to. This arises from the frequent co-existence of the two affections, a fact admitted by almost every pathologist. It is indeed difficult to explain how Dr. Abercrombie has arrived at a very opposite conclusion. In his work on the Diseases of the Stomach and Intestines, he says, "I have been often very much astonished to find in my own observation how seldom the stomach shews marks of inflammation, even when the organs most nearly connected with it have been inflamed in the highest degree."

But in the present state of medicine we cannot admit the opinion of Broussais, that the two affections are always co-existent, as cases are on record which are inconsistent with it. Thus, in the last edition of Andral's *Clinique Médicale*, tom. i., we find the thirty-ninth and forty-second cases are examples of severe gastritis, without inflammation of the intestine; while, on the other hand, the first, third, ninth, tenth, eleventh, nineteenth, twenty-eighth, thirty-fifth, and forty-third cases are examples of enteritis, in some instances very intense, without any gastric inflammation; so that, excluding all doubtful cases, we have in the recorded investigations of a single author, out of fifty-three instances of inflammation of the digestive tube, nine where the stomach remained healthy, and two where this viscus alone was engaged.

I. *Acute gastritis*.—Inflammation of the stomach in its highest degree is rarely met with, unless in cases of corrosive poisoning; but by the study of these we may learn the prominent symptoms of the most violent gastritis, which, when separated from those apparently arising from other causes, are the following: intolerable thirst, constant nausea and vomiting, præcordial distress, sunk countenance, extraordinary prostration, fever. These symptoms, occurring in a case where no poison had been administered, would point out the existence of the most severe gastritis.

The disease, however, occurs with such various degrees of intensity that it is difficult to give any single description of it. In one case it will destroy life with rapidity and with the most dreadful sufferings to the patient; in another it may represent a slight dyspepsia: between these extremes the shades are infinite. In some of the more violent cases there has

been fever, at first inflammatory, but speedily assuming the typhoid type; the patient complains of a burning sensation in the stomach, with ardent, unquenchable thirst, and a desire for cold and acidulated drinks. From the extreme sensibility of the stomach, the fluid swallowed is in most cases immediately ejected, and often the least irritating substances will cause heat, pain, and vomiting. There is generally great tenderness of the epigastrium, so that the slightest touch, the weight of the bed-clothes, or any muscular effort, will produce severe distress. Respiration is accelerated and difficult, although no disease can be detected in the thoracic viscera by auscultation; or if there be, it will not be sufficient to account for the symptom. The patient is restless and anxious; the features are contracted and often distorted, and the prostration of strength (so constant in gastro-intestinal inflammation) is peculiarly marked. Constipation of the bowels occurs,—a symptom common to both acute and chronic inflammations of the upper portion of the digestive tube.

"The symptoms," says P. Frank, "increase with rapidity: scarcely has the patient, with an intolerable burning sensation, swallowed a small quantity of an insipid fluid, than it is rejected, either pure or mixed with eruginous bile. The pulse is small, frequent, contracted, and hard, or intermittent and unequal. The agitation, dyspnoea, restlessness, thirst, and dryness of the mouth go on increasing; hiccup, which greatly aggravates the sufferings of the patient, appears; the extremities become cold; and in some cases delirium and jaundice are observed. In the last stage all sensation of heat and pain in the epigastric region disappears; the flatulent swelling of the belly increases; drinks are rejected by regurgitation, and a serous fluid is often discharged with force; the extremities become as cold as marble, and fainting and convulsions announce the fatal termination."

This is the phlegmonous gastritis of the older authors, as distinguished from the erysipelatous. In modern medicine the terms acute and sub-acute have been substituted. Little advantage, however, is derived from this distinction, as the disease is essentially the same, though occurring under a thousand modifications of intensity.

Patients labouring under severe gastritis often complain of a sensation very analogous to the globus hystericus. They feel as if a round body was rising up and compressing the lower part of the chest; vomiting often relieves this symptom for a time, and hence the patient frequently urges his attendants to give him a full emetic, in the hope of expelling the supposed foreign body, to which he attributes his distress. This sensation is probably caused by spasmodic stricture of the cardia, which may extend to the œsophagus. It has been observed that in some cases swallowing was impossible, and the patients referred the obstruction to the lower portion of the pharynx or upper part of the sternum,—a symptom supposed by Broussais to indicate that the

whole stomach is violently contracted, so as not to admit of any dilatation. This contracted state of the organ has been verified by dissection, the capacity of the stomach having been found reduced to that of a portion of the small intestine.

Connected with the symptom of dysphagia, we may place hiccup, which is one of the most distressing symptoms in these cases: it is most commonly observed in the latter stages of the disease, but we have seen it occurring at the outset, and are led to believe that it then marks a predominance of inflammation round the cardiac orifice. A case of this description lately occurred under our care in the Meath Hospital, in which, after the sudden disappearance of a pneumonia of the lower lobe of the left lung, the patient was attacked with vomiting, followed by severe hiccup. There were extraordinary prostration of strength, thirst, and a craving for cold and acidulated drinks; the epigastrium was tender, and the bowels were confined; the tongue was clean and moist: the hiccup continued incessant even during sleep, though then somewhat modified. Notwithstanding active treatment for the gastritis, death took place on the fourth day of the abdominal disease. On dissection, we found that the inflammatory action was circumscribed in a most remarkable manner for about three inches round the cardia. Here the mucous membrane was of a blood-red colour, thickened and softened, while that of the rest of the stomach was perfectly healthy. The lower portion of the œsophagus was vascular, and the cuticle separated so as to form shreds on the surface of the tube. A similar state of parts was recently observed in another case in Dublin, in which incessant and intractable hiccup was the prominent symptom.

Deep-seated and lancinating pains have occurred in this disease, referred to the epigastrium and hypochondria; and Broussais notices it as an interesting fact, and as indicative of their nature, that they are frequently relieved by cold acidulated drinks. Connected with these painful sensations is another characteristic symptom—the patients constantly throw the bed-clothes off from the chest and epigastrium. This has been supposed to arise from their inability to bear even the slightest pressure on the part, an explanation which may be partly true; but it also seems probable that the desire of cold to the surface is another cause. In some cases we have observed this tendency to be irresistible, although the intellects were perfect: the symptom, however, is not peculiar to gastritis, but occurs in many cases of gastro-enteric inflammation in the acute stage.

The tongue has been described as presenting peculiar characters in this disease; but this appears to be one of those statements taken by writers on trust, of which there are far too many in medicine. Let us examine the state of our knowledge on this subject.

With respect to the question as to whether the state of the tongue indicates any certain condition of the stomach, or *vice versa*, Andral

comes to the following important conclusions:—1. That no constant relation can be established between the state of the tongue and that of the stomach. 2. That there is no modification of the tongue which corresponds with a special modification of the stomach. 3. That a certain state of the stomach may be found after death, with various appearances of the tongue during life. 4. That a morbid state of the stomach may coincide with a healthy state of the tongue, and a healthy condition of the stomach with a diseased condition of the tongue.* Louis comes to almost the same conclusions in his *Recherches sur la Gastro-entérite*. He says, “In most of those cases where the mucous membrane of the stomach presented the greatest lesions, the tongue was generally in its natural state;” and again, page 66, he says, “so that whatever was the state of the tongue, it had not the slightest relation with that of the stomach; the same appearance coinciding with a more or less severe lesion of the gastric mucous membrane in one case, and with the healthy condition in another.”

It may be objected, however, that these observations were made on that class of affections called *fevers*, and that the conclusions would not apply to idiopathic gastritis. But when we recollect the great similitude that exists between cases of idiopathic gastro-enteritis and fever, and also that in other diseases, not of the stomach or intestines, all the morbid appearances of the tongue may occur, it is difficult not to make a general application of the conclusions of the above authors; and M. Piorry† declares that in many cases of well attested acute gastritis the tongue continued pale. From these facts we must conclude that in gastritis no constant state of the tongue exists; this is more particularly true in the less severe and chronic forms of the disease, and in the gastric inflammations which occur in fever. In the acute species and in cases of corrosive poisoning, a red and dry tongue has been often observed, and in some the tongue is glazed and morbidly clean. This state often occurs with a great amount of gastro-intestinal disease. It is of great importance, however, that the researches of Andral, Louis, and Piorry on the relations, in disease, between the state of the tongue and the gastro-intestinal surface should be extensively known, particularly in these countries, where the state of the tongue is so constant a guide in practice, and where, of course, if the conclusions of those authorities be correct, such practice must be often erroneous. It should never be forgotten that a perfectly healthy tongue may and often does coincide with a profound disease in the stomach, and a diseased tongue with a perfectly healthy state of that viscus.

The sympathetic affections in this disease are generally severe and numerous, and in certain cases may become predominant. In

† Journal Hebdomadaire de Médecine, No. 60, 1829.

most instances of acute gastritis there is lesion of the cerebro-spinal functions; and in some, an inflammation of the brain may actually take place. Under these circumstances, we may have the most violent nervous symptoms without our being able to detect by the scalpel any lesion in the brain or spinal marrow; and, on the other hand, the various shades of arachnitis and encephalitis may be thus produced. The two following examples of severe nervous symptoms apparently caused by gastric irritation, and in which no lesion was found in the nervous centres, are so remarkable that we shall not apologize for their introduction.

A patient, aged forty-five, of a strong constitution, entered the hospital of La Charité on the 14th of October, 1820. He was then in such a state of delirium that no account of his former state could be obtained from him. On the morning of the 5th, the following symptoms were observed: eyes haggard, risus sardonius, taciturnity; when the belly is pressed the countenance expresses pain, but the same is observed when pressure is made on any of the limbs; *tongue moist and natural*; respiration free; pulse full, somewhat frequent; some heat of skin. He died in the evening. On dissection, the brain and its membranes were found perfectly healthy; no effusion existed either at the base or in the ventricles. The lungs and heart were healthy, *but the stomach presented several recent ulcerations, with red bases, and between which the mucous membrane was vascular*. In the rest of the canal nothing morbid, except a few red patches, was observed. The other organs were all in their natural state.*

Here we see a pure gastritis, in which the prominent symptoms were those of an inflammation of the brain; and in this case and in that which we shall next quote, a remarkable feature in the history of gastritis is illustrated, namely, *that when the sympathetic symptoms acquire a certain degree of intensity, the more usual, or what may be called the local symptoms, are often either greatly lessened, or altogether wanting*. But this absence of proper symptoms does not indicate that there has been a metastasis of inflammation, or in other words, that the stomach has become healthy.

The next case is also from the same author. A middle aged man, four days before his entrance into hospital, was seized with bilious vomiting, epigastric pain, and fever. In about twenty hours after the invasion of these symptoms, he first perceived a difficulty in depressing the jaw, and a violent trismus was soon established, which continued for the two following days. At the end of this time he entered the hospital in the following state:—trismus, the head drawn backwards and forcibly retained in this position by the muscles which are inserted in the occipital region; rigidity of all the extremities; abdomen hard as a board; the intellect perfect; notwithstanding the trismus, the patient could articulate with suffi-

cient distinctness to give the above account of his case. *From the time when the first tetanic symptoms appeared, the vomiting and epigastric pain ceased*. He died on the evening of his admission. On dissection, no appreciable alteration was found in the brain or spinal marrow; the meninges of the brain were very slightly vascular, but those of the spinal marrow pale. The whole surface of the stomach presented an intense red colour, which was at first concealed by a thick layer of mucosities. The remainder of the digestive tube was perfectly healthy, and the thoracic organs were natural.

There can be no doubt that the condition of the stomach in this case was the result of an intense inflammation, as no other cause for vascularity existed, such as a mechanical obstruction to the circulation. The healthy state of the remainder of the tube, and the accordance between the first symptoms and the condition of the stomach are also of importance with respect to this conclusion.

A patient, aged 30, addicted to the use of spirits, was admitted into the Meath Hospital in March 1832, labouring under violent maniacal excitement; the eyes bloodshot, and the aspect ferocious. He had thirst, a dry and shrivelled tongue, but the belly did not seem tender; the pulse was quick and weak, the bowels were constipated. No accurate history of his previous state could be obtained. The cerebral symptoms increased so as to require the use of the strait-waistcoat, and continued with violence until a short time before death, which occurred on the eighth day after his admission. On the third day the belly was slightly tender, and somewhat tympanitic, and we applied a blister, but without relief. Opium and the cold affusion failed to relieve the cerebral symptoms. On dissection, no appearance of inflammation was found in the brain or its membranes. Some serous effusion existed in the cavity of the arachnoid, but none in the ventricles. The splenic extremity of the stomach was marked with patches of dotted redness, and the mucous membrane softened. The lower half of the ileum, the cæcum, and part of the ascending colon presented marks of intense inflammation, and were studded with numerous ulcerations, some of which, at the termination of the ileum, were of great extent.

We may enumerate the nervous symptoms in gastritis as follows:—prostration, subsultus, coma, all the shades of delirium, headach, intolerance of light, exaltation of muscular force, convulsions, tetanic spasm.

A sympathetic cough, sometimes of great severity, may occur as a consequence of acute gastritis; and, as is the case with respect to the brain, actual disease of the lung may result if the irritation be severe or long-continued, or if the patient have a predisposition to pulmonary disease.

In the *Histoire des Phlegmasies Chroniques* a number of these cases are detailed. In some the disease simulated inflammatory catarrh, and in one pneumonia. The principal symptom was a violent cough, often occurring at each inspiration, and more severe during the exacer-

* Clinique Médicale—Malad. de l'Abdomen, Obs. xxxix.

bations of the fever. In no case did those violent paroxysms occur which, as in pertussis, produce swelling and lividity of the face; but in all this severe cough, "à secousses," continued during the disease, and was sometimes accompanied by a tearing pain. As might be expected, hæmoptysis and many forms of bronchial secretion may be produced—an indication, to use the words of Andral, that the lesion of innervation has been followed by that of circulation and secretion. But notwithstanding these symptoms, so likely to mislead, we have, thanks to the advanced state of medicine, two sources by which a true diagnosis may be arrived at. One of these is the fact, that these pectoral symptoms are more relieved by the treatment of gastritis than by that of inflammation of the lung; more relieved by cold drinks and leeches to the epigastrium than by the use of the lancet. This, any practitioner who has the charge of an hospital will have opportunities of verifying. The second is derived from the use of percussion and the stethoscope, by which, as has been before stated, we find one of two things, either that there is no disease in the lung to account for the violent cough; or, if there be disease discoverable, it is not of sufficient extent or intensity to account for the symptoms.

Under such circumstances, particularly if fever exists, and there is no laryngeal disease, the source of the cough is to be sought for in the digestive system. This sympathetic cough has been long noticed as arising in cases of abdominal irritation, such as worms; but in these countries its supervention in acute gastro-enteric inflammation has not been sufficiently studied. The modification of the principal symptoms of gastritis in this case would greatly increase the liability to error; and the common practice of exhibiting tartar emetic in pulmonary inflammation would, under such circumstances, be followed by the worst results. We have little doubt that, had Laennec lived much longer, he would have altered his opinion as to the safety of this remedy in cases of pulmonary combined with gastric disease; as a very extensive experience has convinced us that even a slight shade of gastro-enteritis is sufficient to contra-indicate the use of tartar emetic in cases of pulmonary disease. In such cases its specific action fails, and the abdominal inflammation is sure to be increased.

Acute gastritis may be accompanied by various forms of fever, so as to represent the inflammatory, ataxic, or adynamic species. Most generally, however, the fever is of one of the two latter types; and it too often happens that the existence of the adynamic symptoms leads to the most erroneous and fatal practice. In the prostration of strength, the petechial eruption, and other analogous symptoms, the symptomatic physician sees nothing but direct debility. The disease is to him a *typhous fever*, and the gastric inflammation is exasperated by stimulation, which adds to the debility by increasing its cause. An extensive knowledge of the state of the science on this subject, a sufficient experience, and a most accurate investigation of the early symptoms, are all necessary

for determining the question. Often has it happened to us to see patients to whom stimulants had been administered with an unsparring hand, notwithstanding a progressive prostration (a circumstance that should have led to a suspicion of the state of parts,) whose life was distinctly saved by the inhibition of all stimulants, the use of ice, and the application of leeches to the epigastrium.

The fever also may be remittent or intermittent. In a case recorded by M^r. Annesley, in which death took place in seven days, the symptoms were constant vomiting and hiccup, with a tertian fever. The patient did not complain of pain. On dissection, the stomach was found studded with small ulcers.

Before proceeding to the consideration of other forms of gastritis in the adult, we shall examine the acute form of the disease, as occurring in infants. Like enteritis, inflammation of the stomach may be an intra-uterine disease, a fact established by the researches of Billard. But we must avoid confounding a congested state of the mucous membrane with inflammation, and this is the more important as congestion of the stomach is common in new-born children, particularly in those who have died by asphyxia. There is, however, decided evidence that gastritis may occur during fetal life. We shall on this subject abridge two cases from the work of the author just named.

A new-born male child died on the evening of his exposure at the Foundling Hospital of Paris, the symptoms being severe crying, almost permanent contraction of the features, and some vomiting of brownish matter. On dissection, the great extremity of the stomach was found eroded by numerous irregularly-rounded ulcerations, which evidently resulted from the destruction of the mucous follicles, as some of these were found but partly ulcerated. The bases of these ulcers were of a bright yellow colour, and the edges, slightly tumefied, were vividly red, so as to form a striking contrast with the rest of the mucous membrane. In this case the author conceives that the development of the gastritis must have been recent, as there was no emaciation, and the disease did not seem to have arrested the progress of the fetal evolution. Billard has frequently seen this disorganization in children who have died shortly after birth, and in whom there was also no emaciation. From these circumstances he is led to believe that when the follicular ulceration of the stomach occurs as an intra-uterine disease, it is most commonly developed during the last days of fetal life.

In the next case the disease was more chronic. A female infant was deposited at the hospital in a pale, emaciated, and feeble state. The exhaustion increasing daily, she was sent to the infirmary six days after birth. On admission, the lower extremities were oedematous and hard, the body pale, the mouth dry, the skin arid and hot, and the pulse very small; there were also bilious diarrhœa, and the signs of hepatisation of the left lung. Death took place in nine days, being preceded for two days by abundant vomiting, which followed the cessa-

tion of the diarrhœa. On dissection the œsophagus was found intensely red and tumefied. The mucous membrane of the stomach was generally white, but in the lower portion of the pyloric third a deep round ulcer, with elevated edges, of a reddish brown colour, was found; this was not surrounded by any inflammatory tumefaction; its base was of a dark colour, and formed by the serous membrane alone. In this case the death is attributable to the pneumonia and œsophagitis, and probably the debility and emaciation to the ulcer of the stomach.

But gastritis is not unfrequent in infants as a disease occurring after birth. It is most commonly complicated with enteritis. Thus, out of one hundred and fifty cases of inflammation of the digestive tube, observed in the Foundling Hospital of Paris, there were ninety cases of gastro-enteritis, fifty of enteritis without gastritis, and only ten of gastritis without enteritis. Four varieties of gastric inflammation have been described as occurring in infants, and the following is Billard's arrangement of these forms of disease:

1. Erythematous gastritis.
2. Gastritis with alteration of secretion.
3. Follicular gastritis.
4. Gastritis with disorganization of tissue.

By the first is implied an inflammation of the mucous membrane, of which vascularity is the principal character; the second is a state of the stomach identical with that of the mouth in the disease called *thrush* in these countries; the third is analogous to the dothino-enteritis of Bretonneau, consisting of an inflammation and ulceration of the mucous follicles; and the fourth comprises gangrene, and the peculiar disease described by Cruveilhier and Guersent under the name of the gelatinous softening of the stomach.

We must not, however, suppose that these forms of disease are essentially different affections. They are all examples of inflammation, varying in degree, in seat, and in result, according to the violence of the disease and constitution of the patient; they may succeed one another, or even occur together, as was the case in the thirty-fourth case of the above author, where erythematous redness, the peculiar alteration of secretion, the follicular ulceration, and the gelatinous softening occurred together. The existence of the second variety has been doubted, but is established by the researches of Billard; it is certainly rare, and was consecutive to the disease in the mouth.

There is but little to be added with respect to diagnosis to what has been already laid down. Vomiting, tension and pain of the epigastrium; painful cries when this region is pressed, and alteration of the countenance, are the principal signs of gastritis in the new-born infant. Should such symptoms arise when the mouth is affected with thrush, it becomes probable that the disease has extended along the œsophagus to the stomach; vomiting of a dark and sanguinolent matter has been observed in the follicular species; but in one respect the

gastritis of very young infants differs from that of the adult, namely, in the almost total absence of febrile reaction.

In the article DENTITION will be found Cruveilhier and Guersent's descriptions of the *gelatinous softening* of the stomach, with the symptoms as observed by them. To this we beg to refer, but in order to embody as much information on this interesting subject as possible, we shall introduce the description as given by Billard.

"The disease generally commences with symptoms of a violent gastritis, such as tension of the epigastrium, which is painful to the touch; vomitings, not only of milk and drinks, but also of a green and yellowish matter, which come on every moment without regard to the time when the child has taken food or drink. There is sometimes diarrhœa, varying in different subjects, and returning after having ceased for a day or two; the matters discharged being often green, like those from the vomiting. The extremities are cold; the pulse is generally irregular, but seldom presenting a constant character; the countenance expresses pain constantly, the face remaining furrowed as if the infant were crying; the cry is expressive of pain, the respiration interrupted, and the general agitation so great that the existence of a cerebral affection might be suspected. To these symptoms succeeds a state of prostration and insensibility from which the child is occasionally roused by pain, when the agitation observed at the early periods of the attack reappears. At length, at the end of six, eight, or fifteen days, and sometimes even much later, the patient sinks exhausted by want of sleep, constant vomiting and pain: in very young infants there is little or no fever."

The result of this disease is the reduction of the mucous membrane to a gelatinous pulp, and such a thinning and softening of the parietes of the stomach that the slightest force will produce a rent. According to Baron and Billard this condition of the stomach is most evident in the greater curvature. In the adult a very analogous affection is observed, to which we shall presently allude.

II. *Chronic gastritis*.—Since the improvement in our knowledge of pathological anatomy, this disease has been found to be much more frequent than was formerly supposed; and numerous instances of what had been believed to be merely dyspepsia, are now proved to be in reality examples of chronic inflammation. Here is one great instance of the improvement in medicine by means of pathology; and in the treatment of these diseases, the tonic and stimulating plan must speedily yield to the judicious employment of the antiphlogistic mode, and a physiological be substituted for an empirical treatment. But we are far from going to the full length of the doctrines of Broussais on this subject. There are too many instances of functional disease of the stomach on record to allow us to doubt that there may be dyspepsia without gastric inflammation; in fact a lesion of innervation without inflammatory action is a

condition common to the viscera, and it would be strange if the stomach formed an exception. It is certain that cases of dyspepsia will mend under a treatment not calculated to remove inflammation; but it is also undeniable that a great number of dyspeptic and hypochondriacal cases, so far from being benefited, are made worse by such a proceeding. The failure of one stimulant or tonic remedy is followed by the trial of another, until the patient sinks; and, on dissection, various results of chronic inflammation are found in the upper portion of the digestive tube. The error of confounding these diseases is one easily fallen into, as in many cases the symptoms are the same, and the fact of chronic gastritis being frequently an appyrexial disease contributes to perpetuate the error. When we consider that in most cases the exciting cause of dyspepsia is an over-stimulation of the stomach, and recollect the law in pathology, that functional seldom continues long without inducing organic disease, we cannot help believing that in most cases of chronic dyspepsia there is more or less of gastric inflammation. Whether this has been the primary affection, or has succeeded to the functional disease, is of comparatively little importance, as its existence is the great point on which turns the success of our treatment. We can assert with confidence, that in numerous cases of chronic dyspepsia, where the fullest trial had been given to the whole class of *stomachic* remedies without relief, the disease has yielded to a strict regimen, with local bleeding and counter-irritation on the epigastrium. Andral, in his *Précis d'Anatomie Pathologique*, declares that, of all the forms of dyspepsia, that from irritation of the stomach is by far the most frequent.—(See the article INDIGESTION.)

In the present state of the science we cannot fix on any symptom sufficient to distinguish chronic gastritis from functional derangement. Painful digestion, loss of appetite, irregular appetite, flatus, eructations, acidity, pyrosis, vomiting, unhealthy states of the tongue, with other symptoms, are common to both; but if the disease be chronic, and if it has resisted the tonic and stimulating plan, the probability of its being a gastritis is almost converted into a certainty. It is scarcely necessary to add, that in the diagnosis the relative frequency of the two affections is never to be forgotten. This point will be fully considered in the article just referred to.

Chronic gastritis occurs with a great variety of symptoms. It most commonly commences in a very insidious manner, and may continue for a length of time without much injury to the general health, and may even coincide, according to some authors, with an increase of nutrition. At this period the disease is too often exasperated by the use of the common anti-dyspeptic medicines; the habits of the patient remain unaltered; and it is not until the symptoms become severe that the disease is suspected. Of these the most frequent appear to be pain and vomiting. The first is commonly felt during the process of di-

gestion, when it is generally severe, and in some cases intolerable; but it subsides either altogether or in a great degree when the stomach becomes empty. The seat of this pain is various, but is generally in the epigastrium or hypochondria, and it may extend to the back. In some cases it is described as being lancinating, in others dull, and may be accompanied by a feeling of constriction and globus, as in the more acute forms of the disease. The epigastrium and left hypochondrium are generally tender, and, when the disease is established, often present a remarkable fulness and resistance to pressure. Vomiting is the next most frequent symptom. In some cases the ingesta alone are rejected, and the vomiting occurs sooner in proportion to the quantity and stimulating nature of the food; but in some severe cases the most unirritating substances are speedily rejected. Great relief often follows the vomiting, and the patient continues comparatively well until he next attempts to take food. Even when the stomach does not contain food, vomiting may occur; and we have known an instance where the patient had acquired the habit of vomiting at will, so as to relieve himself from painful sensations. When vomiting does not occur, the sufferings of the patient are often great. In some instances the process of digestion goes on well, until, as the patient describes it from his feelings, the food arrives at a particular part of the stomach, when pain is induced and the food speedily rejected. This appears more common when the disease is severe but circumscribed.

There is a great variety in the matter ejected. Sometimes there is nothing but an insipid watery fluid; in other cases it is like the white of eggs; it may be intensely acid and acrid; dark-coloured, bilious, or bloody. In one case we have seen a fluid of a blue colour ejected in considerable quantity. Hematemesis is a common attendant on this disease; in some cases proceeding from an exhalation, in others from ulceration of large trunks, as described by Prost; but independent of the latter case, many instances of hematemesis are closely allied to gastritis,—a point of the utmost importance in treatment. Gastritis may commence by hematemesis; will often follow on its suppression, and the treatment of gastric inflammation is that which will most frequently succeed in removing the symptom. The analogy of active hemorrhage in other situations strongly corroborates these views. (See HEMATEMESIS.)

As the disease advances, other symptoms present themselves. In the most severe cases there is complete loss of appetite; but in the less violent this is not observed. The appetite may be capricious, as in pica; and in some instances the taking of food gives temporary relief to a gnawing sensation in the epigastrium. Bulimia has been described as a consequence of this disease, but further researches appear necessary on this subject; and it is probable that the more remarkable

cases of this affection have depended on causes very different from gastric inflammation. Anorexia, however, is one of the most constant attendants on the disease, and many lesions of the stomach may exist without causing any other symptom than a complete loss of appetite.

An exceedingly frequent symptom in chronic gastritis is a constipated state of the bowels; and relief to a certain degree follows the action of purgative medicine. From this circumstance the patient often attributes his sufferings to the constipation; and the same view is too frequently taken by his attendant. What is an effect is considered as a cause, and purgatives are looked to as a means of cure; the disease is allowed to run on until it has passed the reach of art, aggravated no doubt not only by the want of antiphlogistic treatment, but by the acrid substances themselves, which are poured in increasing quantities into the suffering organ. We shall revert to this in considering the treatment of the disease in the advanced stages.

The appearance of the patient is generally characteristic. There is great emaciation, with a countenance expressive of distress, sallow, and with dusky patches on the malar eminences. The skin has a semi-jaundiced appearance, and is at times tightly drawn over the emaciated muscles, so as to resemble that state in horses called *hide-bound*. The tongue presents various appearances, and in this, as in the acute disease, can seldom be considered as indicative of the condition of the stomach. As might be expected, the sympathetic irritations are by no means so well marked as in acute gastritis; but they may all occur. In some cases fever, generally of a remittent character, has been observed.

The disease terminates variously. In some cases death occurs apparently by exhaustion; in others by peritoneal inflammation, induced by a perforating ulcer of the stomach; but its most frequent termination is by extension of disease to other parts of the digestive system, which are generally the duodenum, liver, and spleen: in this way dropsy may be the result of the disease. In other cases the ileum and colon become engaged, and the patients sink from diarrhoea. Fatal vomiting of blood has sometimes occurred, apparently the result of the erosion of large vessels.

It is a remarkable fact that circumscribed gastritis may exist in a manner almost completely latent. Dr. Abercrombie gives a case where the symptoms had been merely those of slight dyspepsia, yet in which fatal perforation occurred from ulceration; and the same author gives, on the authority of Dr. Kellie, an instance of a young and healthy female who had never complained of any gastric symptom, when she was suddenly seized with violent peritonitis, which proved fatal in eighteen hours, and on dissection was found to be caused by a perforating ulcer in the lesser curvature, around which there existed unequivocal marks of extensive and chronic

disease. The patient had resided for four months in the house in which she died, and was never known to have complained of her stomach. Some months previously she had laboured under fever.

It is not uncommon to meet with these circumscribed ulcerations in the dissections of persons who have died of other diseases. Under these circumstances, they are generally either altogether or partly cicatrized, presenting rounded and thickened edges, which are seldom vascular. The base of these ulcers often consists of the serous membrane which has formed adhesions with the liver, pancreas, spleen, or colon. In our dissections at the Meath Hospital we have seen many examples of these. A most remarkable case of communication between the stomach and colon is detailed in the work just quoted. The patient had complained of slight dyspeptic symptoms for some time, when his appetite became impaired; he had some loss of flesh and occasional pain in the abdomen. These symptoms continued for two or three weeks, when he was suddenly seized with fecal vomiting. He felt no further inconvenience for a week afterwards, when he was again attacked in the same manner. This symptom returned frequently for three months, when death took place. On dissection, nearly the whole of the great curvature of the stomach was found ulcerated; in its centre an opening of two inches in diameter, communicating with the arch of the colon, was observed.

As the pathological anatomy of the stomach differs in no respect from that of the intestines, we shall refrain from entering into a description of it here, the subject having been already discussed in the article ENTERITIS, to which we beg to refer. The attention of pathologists has been of late directed to an affection of the stomach in which there is a remarkable softening of its coats. To this we have alluded in describing the gastritis of infants. In the adult it is not unfrequently met with; but though in some cases it is to be referred to a process of inflammation, yet it will often occur under different circumstances. We beg to refer to the writings of Cruveilhier, Louis, and Andral on this subject, and merely remark here, that in the inflammatory species redness generally accompanies the softened state of the tissues.

One of the most interesting and instructive circumstances connected with the history of chronic gastritis is the supervention of acute attacks on the chronic affection. This is often brought about by the use of a too stimulating regimen, but more frequently by the injudicious exhibition of tonic, stimulating, and purgative medicines. It is generally pointed out by the occurrence of fever: the tongue is altered, and the thirst becomes urgent. In other cases which we have observed, there has been no fever, but the appetite has altogether failed, the pain has increased, and the prostration of strength has become alarming. In some cases hemorrhage may take place, which

is followed by great alleviation of all the symptoms.

An interesting example of this aggravation of symptoms occurred to the writer during the last year. The patient was a woman aged 50, who had laboured for nearly a year under the symptoms of scirrhus of the pylorus. In three months after her first illness, a tumour appeared, which, when first seen by the writer, was extensively moveable, occupying the median line, but evidently passing under the left ribs. This had formed adhesions with the abdominal parietes, and in its centre existed an ulcerated opening, through which any fluid taken into the stomach was instantly projected in a small jet. The fistula was closed by a compress and roller; and as the patient seemed almost in articulo mortis, some wine and animal food were allowed. This was followed by burning pain in the stomach, great thirst, heat of skin, a quick and wiry pulse, red and dry tongue, and some delirium. On removing the compress, it was found *that the fluid ingesta did not pass through as formerly*. In the course of three days these symptoms subsided, when the fluids again passed through the fistula: soon after she sunk. No dissection was obtained.

This case is fully reported by the writer's friend and pupil, Mr. William Hamilton, in the *Lancet* of January 28, 1832. He remarks that a fistula thus formed may be closed by inflammation for a time, and hence by analogy it may be concluded that where the intestine is nearly obstructed, it also may become entirely closed by inflammation, and prevent the passage of food; but that, on the subsidence of this inflammation, the passage may be restored.

We shall now briefly examine the question as to whether cancer of the stomach and chronic gastritis are to be considered as identical. In this investigation all the difficulties arise which result from our imperfect knowledge of cancer in general. Supposing that cancer is a new product, and not a mere alteration or transformation of tissue, the question resolves itself into two points:—*first*, does irritation or inflammation, taken in their ordinary acceptance, induce a development of this new matter in the tissues of the stomach? and, *secondly*, may the cancerous matter be deposited independently of any primary irritation, in consequence of a diathesis or disposition of the system at large? In the investigation of the first point we may be assisted by analogy; as for instance, in the case of pulmonary tubercle. That irritation and consequent inflammation does induce this disease in many cases there can be no doubt. How many cases of phthisis commence by a bronchitis; and in what a number of instances are the first symptoms of cancer of the stomach those of a gastritis. In many cases the exciting causes of phthisis are those which would produce inflammation; and the same may be remarked in the case of cancer of the stomach. External cancer is often induced by an injury;

and blows on the epigastrium are enumerated among the causes of the internal disease. Why it is that in one case inflammation will induce cancer, and another not, we cannot explain, any more than why an injury in one person will cause hydatid, in another suppuration, or in a third hypertrophy; or the same morbid influence induce in one continued fever, in another dysentery, and in a third ague.

M. Prus, in his late work on cancer of the stomach, endeavours to draw a distinction between the two diseases, founded more on the exciting causes than on the pathological characters or symptoms of these affections. On this subject he says, "We admit that it is impossible in the actual state of the science to distinguish the organic alterations which constitute a cancer of the stomach from those which are owing to a chronic gastritis."* He also admits that it is impossible to find any distinguishing symptoms between the two diseases, and the indications of treatment which he gives for cancer are essentially those of gastritis; but yet, from the following circumstances, he believes that they are different diseases. He compares the exciting causes of the two affections; but if we abstract those of acute gastritis which he has unfairly thrown into the table, we find that they are essentially the same. Those of gastritis are as follow:—suppression of a sanguineous discharge; excess at table; contusions on the epigastrium; repression of gout, rheumatism, or an exanthem; violent passion. Those of cancer are:—depressing passions; abuse of spirituous liquors; excess in venery; contusions of the epigastrium; suppression of a sanguineous discharge. We submit, therefore, that the exciting causes, as given by this author, are almost completely the same, and that they do not warrant his conclusion, that while those of gastritis act by inducing a sanguineous congestion of the stomach, those of cancer act primarily on the nervous system.

M. Prus lays great stress on the occurrence of pain as an almost constant symptom in cancer. Admitting that it was so, it would form no distinction; but the fact is, that it is by no means so constant an occurrence. On this foundation, and on the relief afforded by opiates, he builds his theory that cancer is a result of a neurosis of the stomach, which he calls "*cancerous irritation*," which is not inflammatory, which is not neuralgic, and differs from a neurosis in this slight particular, that it is followed by lesions of secretion and nutrition! This is merely playing on words.

In the present state of the science we must admit that inflammation may induce that state of the stomach called cancer; and there can be no doubt that when the disease is established, there is always more or less of inflammatory action—a fact of great practical importance, no matter whether the inflammation be primary or secondary. But if cancerous matter, like tubercle, be deposited in other situations, without the necessity of previous inflammation, there

* P. 130.

is no reason why the same should not occasionally occur in the stomach.

Treatment.—The indications of treatment in gastritis generally appear to be as follows:—1. to relieve the inflammation as speedily as possible, so as to prevent disorganization; 2. to avoid every thing that can excite or stimulate the stomach; 3. to moderate the sympathetic affections.

Authors are divided in their opinions as to whether general bleeding be proper in acute gastritis. But if the disease be in an early stage, the patient robust, and the pulse resisting, bleeding may always be had recourse to with advantage,—more, however, as a preparative for leeching than as a direct relief of the inflammation. The previous state of health of the patient must also be considered, as the stronger this has been, the greater will be the benefit from general bleeding. In a weak subject, or in a case where an acute attack supervenes on a chronic gastritis, general bleeding is almost inadmissible.

The great remedy is the application of leeches to the epigastrium, which should be done freely and repeatedly until decided relief is obtained. There are few things more striking in the practice of medicine than the effect of this proceeding in a case of acute gastritis: the vomiting, the burning heat, are often relieved as by a charm; but we have often seen violent cough and delirium subside under the same circumstances. The number of leeches must, of course, be adjusted by the age and strength of the patient, but in this disease injury is more often done from the want than from the excess of leeches. In general, however, gastritis does not require so many leeches as the acute peritonitis. In a robust adult, and where the symptoms are violent, from twenty to forty may be safely applied. In children the number must be regulated by the age. In robust infants four or six may often be applied with safety and benefit. After the leeches fall off, it is better, where it can be done, to apply a cupping-glass, by which more blood is obtained, and the oozing of the leech-bites often prevented, for it is preferable to apply leeches again than to allow the same quantity of blood to be lost by oozing. This rule is peculiarly true in the case of children, in whom it is right to arrest the hemorrhage as speedily as possible. From these circumstances a poultice should not be applied over the leech-bites in infants, or in adults of a feeble constitution; but in different subjects where the fever is high and pulse strong, this may be found serviceable, where its weight does not distress the patient. The best material for a poultice is linseed meal; and as it must be made thin and light, it will require to be changed every three hours. When its weight and heat excites distress, it will certainly do more harm than good, as the practice is then opposed to the instinctive wish of the patient for cold to the part, which has led to the application of ice to the epigastrium in cases of violent gastritis,—a practice which is rational, supported by analogy, and recommended by high authority. In these countries,

however, it has not yet received a sufficient trial.

The bowels, which are commonly confined, are to be relieved by enemata; but on no account is purgative medicine to be given by the mouth. In using injections, it is better to employ those which are not stimulating, though gently laxative; and it is always right to employ the long gum elastic tube, which will seldom fail in giving great relief.

The patient should inhabit a cool airy room, and be removed from all excitement. Cold drinks, such as pure water, iced water, iced lemonade, may be given ad libitum, and in many cases we have given solid ice in considerable quantity and with decided benefit. The older authors recommended that the drinks in this disease should not be cold, from an apprehension that, as cold drinks sometimes excite inflammation, they would be injurious during its existence; but this reasoning is obviously fallacious. Strict watch must be kept to prevent the attendants giving any thing in the shape of a stimulant, whether as food or drink; it is to be recollected that what is innocuous in health may become under these circumstances a deadly poison; for the sensibility of the stomach is so exalted, that the blandest articles will occasionally produce a fatal relapse.

This should be the general outline for the treatment of all cases of acute gastritis. Let the practitioner recollect that all the symptoms proceed from an inflamed state of the stomach, and consequent excitation of its sensibility and sympathies, and avoid the practice of prescribing a medicine for every symptom. Let him combine all his efforts to subdue this inflammation, and do nothing which can possibly interfere with this indication.

Effervescing draughts are commonly used in cases of irritability of the stomach, but in gastritis they often fail altogether in relieving the vomiting; and when this is the case, there is little doubt but that they exasperate the disease. Even when they remain on the stomach, it does not follow that they are beneficial; in several cases they do injury, partly by their direct stimulation, and partly by the mechanical distention of the stomach. They may be used, though with caution, in cases of mild gastro-enteritis, where the disease predominates in the lower portion of the intestine.

In the early stages of the disease, and always where leeches have not been applied, blisters are improper, particularly when applied on the abdomen; in those cases, however, where the disease has followed the retrocession of an exanthem, they are perhaps more admissible. If they are used in the ordinary gastritis, it should be in the advanced stage, and never allowed to remain after pain is excited.*

The use of emetics has been resorted to in the early stages of this disease, but is a practice full of danger. P. Frank declares that an emetic is in general fatal in gastritis; but this perhaps is going too far. In some of the very mild shades of the disease, an emetic may be

* See the article DERIVATION.

attended with advantage, and is also useful and indeed necessary when the disease has resulted from an excess at table, and supervened while the stomach was loaded with undigested food. But as a general treatment we are decidedly opposed to the emetic plan, particularly to the use of antimonials, which are peculiarly injurious when any degree of gastritis exists. The remarks made on the use of purgatives in enteritis* apply nearly to that of emetics in gastritis.

After the violence of the attack is over, and the patient convalescent, the greatest attention is to be paid for a length of time to his regimen. This is of all cases that in which an error in diet is most to be feared; as an excited sensibility of the stomach remains after the inflammation has subsided. Farinaceous substances, with the mildest broth and vegetables, should constitute the patient's food for a considerable period; and if any fixed pain should continue in the region of the stomach, even though the general health and appearance of the patient be improved, the efforts to remove this should be incessant, as it most frequently depends on a circumscribed inflammation, which, if not relieved, may terminate in an incurable ulceration. The means best calculated to remove this symptom are a strict regulation of the regimen, and counter-irritation on the epigastrium.

Facts are still wanting to establish the efficacy of mercury and opium in this disease. From what we know of the stimulating effects of calomel on the gastro-intestinal surface, it seems probable that its use in gastritis would be often injurious, or at least hazardous. It has been said that large doses of calomel have succeeded in arresting obstinate vomiting; but the cessation of a single symptom by no means implies the removal of the disease, or even its alleviation. If ptyalism were speedily induced, we have reason to believe that the result would be favourable; but all practical men know that in a severe inflammation this is a matter of great difficulty or even impossibility, and the chance of our succeeding in the attempt does not warrant any measure that may compromise the safety of the patient. If mercury be used, it should be by inunction.

The treatment of chronic gastritis is founded of course on the same general principles as that of the acute species. It may be considered under two heads—the *curative* and the *palliative* treatment; the first to be adopted in cases where there is a chance of cure; the second where the disease has passed the reach of art. We believe that, if there is a disease more frequently mistaken and maltreated than another, it is chronic gastritis. The general practice in this disease is really the opprobrium of medicine, as in the great majority of cases it is not recognized, but considered as a mere functional affection. It is called dyspepsia, hypochondriasis, liver disease, torpor of the biliary organs, constipation, any thing but its proper name. The effect of all this is, that almost every attempt at cure in reality exasperates the disease. Bit-

ters, tonics, aromatics, antacids, acids, nervous medicines, iron, arsenic, bismuth, mercury, and purgatives are given in turn; and who can wonder if cancerous ulceration or incurable disease of the solid viscera be the result of such a treatment?

In chronic gastritis the cure is principally to be effected by a long attention to the diet of the patient, which should be as sparing as his strength will allow, and consist of the least possible exciting articles of food. By this simple and physiological mode, by which nature is allowed to exercise her full powers, cures have been performed in cases where great emaciation had occurred, and where the skin had assumed the peculiar hue so characteristic of abdominal disease. Such a result, however, can be rarely hoped for under such circumstances.

We have succeeded in many cases by this mode, and by the repeated application of small numbers of leeches on the epigastrium. The bowels were kept open by injections, and no medicine whatever given by the mouth. In addition to these means, a blister and frictions with the tartar emetic ointment were employed with decided benefit. In the treatment of this disease we are encouraged to persist in these means from the knowledge that ulcers of the stomach may become cicatrized, and a permanent cure be thus produced. The case of the celebrated Beclard is an interesting example of the effect of a physiological treatment. He was attacked with symptoms of gastritis, which after some time assumed the chronic type. He had then frequent pain, and vomited most of his food; he restricted himself to a severe regimen; occasionally applied leeches, and used the tartar emetic ointment. For a length of time no permanent relief was obtained, but he persisted in this treatment, which ultimately proved successful. After his death, which occurred from a disease of the brain, a cicatrized ulcer was found in the smaller curvature of the stomach; its edges were neither red nor tumefied. The rest of the stomach was healthy.

But are we to believe that tonics should never be employed? Facts are wanting to clear up this question; yet, if we reason from analogy, we should admit that after the disease has been modified by a proper antiphlogistic treatment, such remedies might be applicable. There is at least one case where they seem useful; where, after the prominent signs of disease have been removed, the powers of the stomach do not regain their former strength; but even in this case they are to be used with caution. The great source of injury is the practice of prescribing for symptoms, without connecting these with the pathological state of the viscus; a practice which must always prevail so long as pathology is not more extensively cultivated.

The palliative treatment consists essentially in avoiding over-stimulation, and in the use of the narcotic remedies. Many cases are on record where these have given great relief for a length of time. Those which we have known to answer best are the hydrocyanic acid, and the acetate of morphia. For instances of the effi-

* See the article ENTERITIS.

cacy of the narcotic remedies in chronic stomach affections, we would refer in particular to Dr. Bardsley's late work.

In these incurable cases the distressing symptoms of flatus, acidity, &c. must be met by palliatives, as we cannot hope to remove their cause. We beg to refer to the articles INDIGESTION and CANCER OF THE STOMACH for information on these points.

(William Stokes.)

GASTRODYNIA, from *γαστήρ*, ventriculus, the stomach, and *δύνη*, dolor, pain.

Pain of stomach occurs as a symptom of several diseases. It is often expressed by the term *gastralgia*, but this seems to be used rather in a general sense to denote mere pain of stomach, from whatever cause arising, than as designating any specific malady. Indeed, to comprise under one general head all pains which affect the stomach would bring together morbid conditions so heterogeneous, or at least so remotely allied, that no advantage could accrue either to nosology or practice from such a combination. Many pains are but symptoms of other diseases, in connexion with which they are most appropriately and beneficially discussed. In the present article it is not proposed to treat of all pains of stomach, but principally of one form of such complaint which has long been regarded as an individual disease, and has had a specific character assigned to it in nosological systems, under the denomination prefixed to the present article.

There is a convenience, especially for recording and communicating practical knowledge, in assigning a certain individuality to diseases, designated by brief and comprehensive terms, and so far nosology has its use. But there are also evils attendant on such arrangements which should be kept steadily in view, else they are very liable to mislead, and to divert attention from the only source of real knowledge, the examination of those morbid actions and structural lesions which constitute diseases, and by the minute scrutiny of which alone can we ever acquire just notions of their nature or treatment. A name is not altogether unimportant, for if not founded on the essential derangement, but derived from a contingent symptom, it conveys a false notion, which, to the young and inexperienced at least, is not harmless, tending to contract their views at that period of life when the spirit of inquiry is most active, and very likely to give a bias to their maturer judgment. Early impressions sink deep; early experience being directed by them is apt to confirm them; the active business of life does not always afford time or opportunity for investigating or correcting fundamental misconceptions; and thus a prejudice, engendered by a mere name at the commencement of professional life, may endure to its close. The history of physic affords abundant evidence how tardily early prejudices and misconceptions yield to the force even of demonstrative proof; of which the reception which Harvey's discoveries met from his contemporaries may be adduced in illustration.

Pain of stomach is not properly a disease, but a symptom attending diseases which have their seat in the stomach, or which sympathetically affect it. The evil of regarding the pain as identical with the disease, is that, on this presumption, whatever has the power of allaying the pain must be deemed the appropriate remedy for the disease, an error which has given rise to much mischief, and which more extended investigation of the real nature of the disease fully exposes.

Nevertheless, in the present state of our knowledge, we must follow the denominations of diseases generally received, and no injury need result so long as the name is not suffered to decide the pathological character, nor to repress inquiry into those morbid actions or conditions to which remedies, to be effectual, must be directed.

The pain of stomach, which is the main subject of the present article, is generally regarded as a mere symptom of dyspepsia. Its great prevalence, however, the suffering which it causes, the interruption of healthy function which it indicates, its long durations, and the structural derangements that may ensue from erroneous or inefficient treatment, entitle it to a separate and independent consideration.

In Cullen's nosology gastrodynia has no place, save as a symptom of dyspepsia. Sauvages and Sagar, who regarded it as a distinct and specific malady, have each distinguished it by a definition; that of Sauvage as "*quicunque dolor notabilis et constans in regione ventriculi, qui continua animi dejectione non stipatur ut cardialgia, nec pyrexia ut gastritis.*" Sagar's, though more brief, is similar; "*notabilis et durans in regione ventriculi dolor, sine syncope et pyrexia.*"

Persons affected with this malady evince generally more or less of dyspeptic derangement. The sense of pain, however, overpowers every other feeling, and is represented as the sole complaint; the contingent ailments being acknowledged only on enquiry being pursued. So variable is the pain, both in intensity and duration, that it would be difficult to furnish a description which would comprise all its gradations. It is characterised as an obtuse pain, giving the sensation of the stomach being forcibly compressed. There is oftentimes tenderness on pressure at the ensiform cartilage, a sense of stricture across the lower part of the chest, with pain extending to the back, and impeding respiration; all marking the diaphragm to be implicated. In general the pain occurs more particularly at certain times of the day, lasts for some hours, and subsides. These attacks are more or less frequent, more or less durable. Sometimes the intervals of abatement are so inconsiderable that the pain is represented as lasting all day, although on enquiry the usual remissions will be found to have occurred. The disease is oftentimes met with unattended by any other indication of impaired health, the pulse being calm, the skin cool, and the tongue clean. Generally the tongue is more or less loaded; and in some a quick pulse and hot skin mark the co-exist-

ence of a febrile state. This last condition is not a frequent concomitant, and may be regarded as accidental, not being necessarily produced by or connected with the primary affection; yet it may have relation to the mucous membrane of the stomach passing into a state of inflammation, as will be hereafter noticed. The spasmodic character of the pain and the absence of fever have misled practitioners into much inefficient and injurious practice in this complaint. Stimulants, narcotics, and other antispasmodics have been freely given; yet notwithstanding the power which such remedies unquestionably possess of allaying the pain, there is good reason to believe that their use is not suitable for the cure of the disease,—nay, that, however they may temporarily alleviate, they, if solely relied on, tend in reality to confirm it, and render it more inveterate.

If the views of the malady about to be presented in this brief essay be correct,—and they are the result not of slight observation, but of extensive experience in this special disease, which prevails much among the poor,—the use of such remedies must be superseded by more rational and effective treatment.

The brief account already given of this disease is almost enough to characterise it. In the commencement the pain is generally slight and transient. Accompanied, as it frequently is, with flatulency, this is conceived the cause of pain; and as cordials and carminatives give relief, they are chiefly resorted to. Warm purgatives are apt to be employed; and as they both stimulate the stomach and evacuate it downwards, they are still more beneficial. Unless the disease, however, be very slight indeed, these remedies are inadequate to afford effectual relief. In time the attacks of pain recur more frequently, are more violent, and of longer duration. In this stage it is that opium, ether, and such remedies are resorted to; and as they have the power to lull the pain, their appropriateness is seldom questioned. On recurring attacks they are again employed, and with greater freedom; for the more such remedies are used, the larger must the doses be to produce the required effect. Thus recurring and thus treated, the disease leads in time to a variety of derangements, both visceral and nervous. Digestion becomes progressively more depraved, nutrition fails, and the body wastes; the strength declines, and the patient eventually sinks from exhausted constitution, if his fate be not hastened by some coincident or superinduced disease. Very different is the result when the early disease is treated on principles deduced from its real nature, and from that condition of stomach in which it originates.

So obviously spasmodic is the pain of gastrodynia, that, the real nature of the disease being unsuspected, it is not surprising that it should be regarded as essentially spasmodic, or that antispasmodic remedies should have been trusted to for its relief. The alleviation of pain, too, obtained by stimulants and narcotics was well calculated to confirm the pre-

vailing notions, and establish the practice founded on them as the most judicious that could be employed. Yet admitting the existence of spasm, it surely merited enquiry why this spasm should occur, and what causes could excite it. That the muscular coat of the stomach should be affected to this extent by any primary depravation of its own fibres was at least not probable, the supposition being inconsistent with the general state of health, which, in the outset at least of the disease, persons affected with gastrodynia ordinarily display. Some special irritation ought to have been suspected, and had this been sought in the condition of the mucous membrane of the stomach, and of its secretions, it could not long have eluded detection.

That in gastrodynia the mucous secretions of the stomach are redundant and unhealthy is sufficiently demonstrable. If emetics be given, this mucus is copiously discharged, of a quality to shew that it was not of recent formation. Instead of being fluid and pellucid, it is dense, membranous, and opaque, unlike in all respects to that which a healthy stomach discharges on the operation of an emetic. The difficulty, too, which the stomach experiences in detaching and expelling it is proportionally great, and the effort is oftentimes severe. The stools also are loaded with mucus, to which a corresponding state of the mucous membrane of the intestines no doubt contributes. The presence of this mucus evinces a previous excitement of the membrane secreting it, and in this irritation we may reasonably conceive the primary disease to exist. It is only, however, when the mucus thus formed accumulates and oppresses the stomach, that the spasmodic pain occurs; and when the foregoing facts are considered, in conjunction with the relief which suitable evacuants afford, it is difficult to resist the conclusion that the pain arises from a contractile effort of the stomach to detach and expel the offending matter. This view may be deemed conjectural, and in some respect it is so, resting for its truth rather on inference than demonstration; for as gastrodynia, at least in its earlier stages, does not destroy life, necroscopic observation, even if it could detect such morbid condition, cannot be referred to in proof of the lesions thus supposed. Yet it is a rational conjecture, and fully supported by all that we know both of the physiological nature of the parts concerned, of the phenomena of the disease, and of the effects of medical treatment. But we are not without direct evidences of the morbid condition of the mucous membrane here inferred, although they are not connected with the disease under consideration so as to make them available for directly illustrating it. All pathological anatomists who have investigated minutely the lesions of the gastro-intestinal mucous membrane, bear ample testimony both to the frequency of vascular congestion, and to the abundant mucus connected with it. In respect of the latter, Andral says, "on opening dead bodies one is sometimes struck with the prodigious quantity of mucus

on the internal surface of the stomach and intestines." Again he remarks, "we find vomiting produced by all possible degrees of irritation of the gastric mucous membrane, which cause the patient to throw up food and drink, or else the bile which had previously been attracted by the irritation of the stomach. In other cases the matter vomited consists of blood exuded by the irritated mucous membrane, or of mucus secreted in superabundant quantity, which last by accumulating becomes a kind of foreign body, and produces by its presence secondary irritation more considerable than that to which it owed its existence." The vascular congestion has been distinguished as existing in the capillaries, in the larger vessels leading to them, or in both. The hyperæmia of the capillaries is regarded as arising exclusively from irritation; and as these pervade the mucous follicles, and are in fact the source from whence mucus is secreted, there seems to be little difficulty in perceiving how irritation must almost of necessity beget an increased secretion of mucus.

If then, as appears, irritation occasions increased secretion of mucus, and if this mucus is capable of accumulating and of becoming a kind of foreign body, producing by its presence a secondary irritation more considerable than that to which it owed its existence, we have the elements of that pathology which long and patient observation of the effects of medical treatment has led us to assign to gastrodynia. What the precise affection is to which French practitioners give the name of "embarras gastrique" we are not aware, but many circumstances in the following extract from Andral shew that it is nearly allied to that morbid condition of stomach which prevails in gastrodynia, and of which spasmodic pain is only a contingent symptom.

"There is a peculiar morbid state of the stomach that has long been distinguished by French practitioners by the name of 'embarras gastrique,' the nature of which is far from being well known. It is characterised by a certain assemblage of symptoms local and general, does not yield at all to bloodletting, and but slowly to diet, while it readily gives way to emetics and purgatives. That the symptoms which attend this affection are often connected with irritation of the stomach, and that they are exasperated by tartar emetic, has been proved by experience; but that it is in every instance merely gastritis, and not a disease of another kind, and requiring a mode of treatment as peculiar as the symptoms that announce it, is a conclusion totally incompatible with observation. It may be presumed that one of the causes of the affection is an alteration of the mucous secretion of the stomach, and I do not see why such an alteration should be considered as necessarily the result of irritation, unless we choose to allow that the mucous coating which sometimes covers the tongue necessarily indicates glossitis." It is clear that the term irritation in the foregoing passage is used to express, not the simple irritation which merely excites increased secretion, but the

more active state into which this occasionally passes, and which, when advanced to inflammatory action, constitutes gastritis.

From the foregoing discussion it will, we think, be admitted that the researches of pathological anatomy are at least not opposed to that pathology of gastrodynia which assigns the spasmodic pain to the presence of offending mucus, and the efforts of the stomach to get rid of it. Irritation is no doubt the primary affection that leads to increased secretion of mucus, but it is to the secondary irritation caused by this mucus when redundant and accumulated, and to the efforts which the stomach thus exerted makes to throw off into its cavity what offends it, that the peculiar pain of gastrodynia must be referred. The spasmodic nature of these efforts accounts for the alleviation of pain produced by opium and stimulants, and the cause not being thus removed, we at once understand why such relief is but transient and ineffectual. The perfect relief desirable from suitable evacuates, without any aid whatever being required from narcotics, proves unequivocally how much more concerned the offending matter is in causing the pain, than is the muscular coat of the stomach which this matter so grievously disturbs, and which needs only to be freed from the disturbance to return at once to healthful quiescence, and, if the primary irritation have ceased to operate, to that ordinary exercise of functions which in health is so tranquil as not to be a subject even of consciousness.

On these principles, then, the cure of gastrodynia requires that the mucous membrane be freed from the redundant secretion with which it is loaded and oppressed, and that a healthful state of the secreting membrane be established so as to guard against renewed accumulation. And here it may be remarked that accomplishing the former purpose ministers to the latter; for when the accumulated mucus is dislodged by suitable evacuates, not only is a direct source of irritation removed, but the secreting organs are restored to a more effective exercise of their functions, by which the primary irritation, and the congestion consequent to it, are best and most effectually relieved. The effect of irritation is congestion of bloodvessels with hyperæmia of the capillaries, and these beget increased secretion from the mucous follicles by which the overcharged vessels are unloaded, and the natural cure of the disease effected. When these conditions and natural changes are clearly understood, the treatment of the disease becomes simple in the extreme; and if the success of others in treating the malady on the principles here inculcated but equal what the writer of this essay almost daily witnesses, he will have little apprehension either of the pathology here advanced being rejected, or of the practice enjoined being condemned.

It may throw some light on the subject to consider the circumstances which tend to excite and vitiate the gastric secretions so as to induce this form of disease. Though luxurious living is a fruitful source of gastric disturbance, yet gastrodynia is not the most frequent conse-

quence of such indulgence. Much more generally does the disease assail the poor and ill fed, amongst whom it is very prevalent. How far it is caused in them by poverty of diet or by abuse of stimulants, it would be difficult to determine. Our own impression is that the former cause is most influential. A poor vegetable diet, when taken for a constancy under circumstances that would demand food of more nutritive quality, weakens digestion, as is evidenced by flatulency, acid eructations, heartburn, and other dyspeptic manifestations. Whether as cause or consequence of these disturbances, irritation of the mucous membrane may be presumed to exist. We have seen that irritation begets hyperæmia of the capillaries; that this leads to increased secretion of mucus; that this mucus is capable of accumulating and of acting as a foreign body, inducing a secondary irritation; and that it is this secondary irritation which is the most probable exciting cause of that spasmodic pain which characterises gastrodynia. Deficiency of food may be readily conceived to produce similar effects. However this be, (for we contend not for the conjectural expositions thus hazarded) the important fact is, that in gastrodynia the mucous secretions of the stomach are redundant and depraved, and that the removal of this offending matter, and the re-establishment of moderate and healthy secretion, are the essential means of cure. It may be objected that the evidences of redundant mucus are not always demonstrable; that the practice resulting from this theory is often inapplicable if not injurious; that remedies very different from those which we enjoin succeed in giving relief. To these representations we would reply, that if the causes assigned be proved to exist in the more exquisitely formed cases, a fair analogy justifies an extension of the same reasoning to the slighter shades of the same malady,—that the term pain of stomach is so vaguely applied, that the most opposite conditions of that organ are incongruously classed together under it, to all of which the same treatment cannot be suitable,—and that when remedies the opposite of those which we enjoin succeed best, the disease will on investigation be found to be of a character very different from that which belongs to the subject of this essay. We are aware that pain attends a state of stomach marked by high irritability, sickness, vomiting, with other corresponding symptoms; and that this is best relieved by soothing remedies, and often by the suspension of all irritation, perfect abstinence being often the best of all remedies. Castor-oil as an aperient, cooling salines, prussic acid, will here give relief, when drastic purges or cordial remedies would exasperate. But this disease is essentially different from the one now treated of: it is acute, while pure gastrodynia is chronic. The pain is continuous, while that of gastrodynia occurs in paroxysms. Its consideration, therefore, belongs rather to the head of gastritis than of the disease now under discussion.

The reference to a poor vegetable diet, and to a deficiency of nutriment as giving rise to that

condition of stomach which produces gastrodynia, would serve to explain why this disease among the poor is in general so little liable to pass into inflammation, and also why the combination of cordial remedies with purgatives is still so eminently serviceable. The supposition, however, of vegetable food being unsuited to dyspeptic ailments is often egregiously misapplied when these occur among the higher classes of society. Such patients are continually enjoined to live almost exclusively on animal diet, all vegetable matter being interdicted as if it were poisonous. This is a great misconception, for if a due admixture of vegetable food with animal be not borne by the stomach, there is always something to correct which no precision of mere diet will ever thoroughly rectify, while an exclusive use of animal food begets evils far more serious than any to which mere dyspepsia can ever give rise. A brief case may illustrate this. A delicate female suffered long from what was called weak stomach, and was enjoined an animal diet, all vegetables being prohibited. Experiencing some relief, she pursued this system until increasing plethora induced determination of blood to the head, ending in violent epilepsy. By active discipline this was relieved, and it afterwards became necessary to restrict the animal diet and return to vegetable. The stomach, improved by the depletion and other evacuant treatment required for the epilepsy, now bore vegetable food without inconvenience, and in getting rid of her epilepsy she became released also from her dyspepsia. In gastric derangements, therefore, the general state of constitution should be regarded no less than the local ailments. If plethoric, depletion with low diet will be most suitable; if low and impoverished, depletion will of course be improper, save the evacuations which the special derangement may require; and sustenance must be more liberally allowed. It is of importance, however, that no mistake be committed in this respect, and that the deceptive feebleness which frequently attends and results from a plethoric state of constitution, be not confounded with pure debility arising from insufficient nutriment; of which subject a full elucidation will be found under the article PLETHORA.

As evacuation of the stomach and bowels by suitable purgatives forms an essential part of the treatment of gastrodynia, it becomes expedient to offer here a few remarks on the differences of operation observable among purgative medicines, as a guide to the judicious selection and adaptation of them to the cure of this complaint.

In considering the operation of cathartics, it is necessary to bear in mind that the stomach forms part of the alimentary canal, and that, although emetics are its more immediate evacnants, it both requires to be cleansed, and admits of being so by means of suitable cathartic medicines. In the operation both of emetics and purgatives some well-marked differences are respectively distinguishable. Of emetics, some merely eject the floating contents of the stomach, while others cause

it to throw off also its mucous secretions. Examination of the matter discharged by vomiting furnishes abundant evidence of this fact. In the operation of purgatives there is a still greater variety; and these, though divided generally into cathartica mitiora and aciora, or laxatives and purgatives, seem to admit without violence of still further distinctions. Some merely carry forward the foul contents, gently exciting the peristaltic motion of the intestines, and thus emulating the natural processes; others, in addition, act on the exhalent arteries, producing copious watery stools; and a third class, while they expel feces, and are capable of producing liquid stools, have the further power of emulging the follicles which line the mucous membrane, causing them to throw off the redundant secretion which adheres to and oppresses them. When the bowels are merely inactive, their secretions healthy, and no constitutional disease present, simple aperients of the first sort suffice to obviate costiveness, and prevent feculent accumulations; medicines of the second are necessary when, besides unloading the bowels, it is required to allay fever and abate arterial action by reducing the volume of the circulating fluids; those of the third are called for when, in consequence of increased action in the vascular system, or of special irritation, the natural mucus of the stomach and intestines is inordinately secreted, or when it becomes viscid and of morbid character, so as, by its special irritation, to give rise to or aggravate disease.

The special medicines belonging to each class will naturally suggest themselves to every practitioner. A precise arrangement of them on the principle here noticed is not required, and would serve no useful purpose. The same medicines act differently on different constitutions, and it is to the effect rather than to the medicine producing it, that attention should be directed. Castor-oil, sulphur, manna, and such like, are medicines of the first class; to the second, chiefly, the saline aperients are to be referred; and to the third various vegetable cathartics, such as aloes, colocynth, jalap, &c. variously combined with each other, and, as occasion requires, with certain metallic salts and oxides, which powerfully aid their operation. These salts and oxides are principally of antimony and mercury, which in their effects on the gastro-intestinal mucous membrane differ more in degree than in kind; each, while it affects more particularly one part of the canal, being capable of exerting its influence on the whole. Thus tartarised antimony, the more immediate effect of which is to excite vomiting, with discharge of mucus from the stomach, is also well known to purge; and calomel, chiefly used, when given with cathartics, to increase their purgative effect, often excites sickness and vomiting. These facts are important for guiding us to a discriminating use of purgatives in the cure of gastrodynia.

The spasmodic pain of this disease being traceable to the irritation caused by redundant

and vitiated mucus, and the discharge of this proving the most effectual means of relief, it is obvious that to whatever antecedent deviation from health its production may be owing, the first indication is to effect its removal by well-adopted evacuants. Various auxiliary remedies are no doubt valuable, and of these several will be noticed; but it cannot be too deeply impressed that unless the main object of removing the offending cause be accomplished, all means which act merely by allaying pain must prove of transitory effect, if not wholly abortive. And here we may cursorily remark, that however the practice inculcated in this essay may seem to flow from the theory proposed, it was not originally derived from it; on the contrary, it was from the signal success of the practice, with close and patient observation both of the phenomena of the disease and the effect of remedies, that the theory was deduced. From the pathology advanced, it might seem to follow that emetics, and especially those which dislodge the mucous secretions of the stomach, would be the direct and appropriate means of cure. Such remedies are no doubt applicable, but in the larger portion of such cases milder treatment will fully suffice. Besides, though pain of stomach is the prominent symptom, disease is not confined to this viscus, but extends along the intestinal tube, the secretions of which evince a state of vitiation corresponding to that of the stomach, whence a necessity exists for cleansing not only the stomach but the whole intestinal canal; and this is most effectually done by combining remedies which are capable of acting on every part of it. The combination which effects this purpose most completely is colocynth, or any similar drug, united with calomel and tartarised antimony in due proportion. After what has been said, the rationale of its operation can need no further explanation.

In the form and degree in which the disease ordinarily presents itself, very mild treatment suffices to remove it; yet if this be not employed, it may continue to harass the sufferer for months or years. A few active purges, of colocynth and calomel, with or without the addition of antimony, cleanse the stomach and bowels, while mild cordials given in the intervals relieve flatulency and abate uneasy feelings.

In hundreds of cases treated at the Bath United Hospital, the common cathartic pill of the house (composed of four grains of colocynth and one of calomel), and a form of cordial mixture which has been in use there for half a century, are the only remedies required; and by means of this simple treatment relief is afforded almost uniformly, and within a very short time. At first the stools are almost always dark, foul, and slimy; and it is interesting to observe how improvement of stools and decline of symptoms keep pace with each other. So long as the stools continue foul, the disease does not thoroughly yield, nor can the use of remedies be relinquished; and it is of importance to attend to this connexion,

for if consciousness of recovery induce the patient to forego the use of medicines ere healthy stools be re-established, either renewed disease or impaired general health will inflict the penalty of his precipitancy.

We are no advocates for the continued use of medicines however mild, but much experience has satisfied us that until a state of healthy secretion be established in the intestines, especially after long derangement of their functions, there is hazard in foregoing the assistance which nature requires. Two of the cathartic pills above mentioned, taken every other night or twice a week, operate in general as much as is needed. But such patients are frequently so costive as to have no stools but by means of the pills, and need aperients in the intervals. For this purpose the common black draught may be given; but when such costiveness prevails, it becomes expedient, after a few doses of colocynth and calomel, to give every night, or night and morning if necessary, colocynth, aloetic pill, or any corresponding aperient, to the necessary extent. An excellent combination for this purpose is colocynth conjoined with henbane; two parts of the former to one of the latter. While the purgative treatment is pursued, much relief is afforded by the daily use of the cordial mixture already noticed; and so valuable has this been found as an adjuvant, that it may not be amiss to give here its precise formula. It is the *mistura salina cardiaca* of the hospital pharmacopeia. By whom it was introduced we have been unable to trace, but it has been in constant and extensive use for upwards of half a century; and though the simplicity and apparent inertness of the compound may excite a smile, we can faithfully declare that we know not a more valuable adjuvant wherever purging, such as we have described as necessary in gastrodynamia, is required for the correction of intestinal derangements. It is valuable, too, in many other disturbances of gastric and intestinal functions, which it would be foreign to our present purpose to discuss. The mixture is thus prepared:—

R Sodæ subcarbonatis, ℥i℥.

Aquæ puræ, Ovi℥ss.

Acidi sulphurici diluti, ℥i.

Confectionis aromatici, ℥iii.

Spiritus menthæ piperitæ, ℥iii.

The foregoing quantities thus combined yield 324 grains of sulphate of soda, 423 grains of the subcarbonate remaining unaffected by the acid. Thus each ounce of the mixture contains but a few grains of either salt; yet, insignificant as the dose may appear, it is not inert. It is very possible that practitioners often err, especially in the treatment of chronic maladies, from requiring an obvious effect from each dose administered; and that where it is ascertained that a medicine actual possesses inherent powers, the slow and almost imperceptible exercise of these powers should not be despised. There is often more wisdom in seconding the efforts of nature than in superseding them. When offending matter is to
